Chapter 1

Building a Secure Organization

John Mallery
Mallery Technical Training and Consulting, Inc.

It seems logical that any business, whether a commercial enterprise or a not-for-profit business, would understand that building a secure organization is important to long-term success. When a business implements and maintains a strong security posture, it can take advantage of numerous benefits. An organization that can demonstrate an infrastructure protected by robust security mechanisms can potentially see a reduction in insurance premiums. A secure organization can use its security program as a marketing tool, demonstrating to clients that it values their business so much that it takes a very aggressive stance on protecting their information. But most importantly, a secure organization will not have to spend time and money identifying security breaches and responding to the results of those breaches.

As of December 2011, according to the National Conference of State Legislatures, 46 states, the District of Columbia, Puerto Rico and the Virgin Islands had enacted legislation requiring notification of security breaches involving personal information. In 2011, 14 states expanded the scope of this legislation.[1] Security breaches can cost an organization significantly through a tarnished reputation, lost business, and legal fees. And numerous regulations, such as the Health Insurance Portability and Accountability Act (HIPAA), the Gramm-Leach-Bliley Act (GLBA), and the Sarbanes-Oxley Act, require businesses to maintain the security of information. Despite the benefits of maintaining a secure organization and the potentially devastating consequences of not doing so, many organizations have poor security mechanisms, implementations, policies, and culture.

1. OBSTACLES TO SECURITY

In attempting to build a secure organization, we should take a close look at the obstacles that make it challenging to build a totally secure organization.

1. http://www.ncsl.org/issues-research/telecommunications-information-technology/security-breach-legislation-2011.aspx (February 2, 2012).

Security Is Inconvenient

Security, by its very nature, is inconvenient, and the more robust the security mechanisms, the more inconvenient the process becomes. Employees in an organization have a job to do; they want to get to work right away. Most security mechanisms, from passwords to multifactor authentication, are seen as roadblocks to productivity. One of the current trends in security is to add whole disk encryption to laptop computers. Although this is a highly recommended security process, it adds a second login step before a computer user can actually start working. Even if the step adds only one minute to the login process, over the course of a year this results in four hours of lost productivity. Some would argue that this lost productivity is balanced by the added level of security. But across a large organization, this lost productivity could prove significant.

To gain a full appreciation of the frustration caused by security measures, we have only to watch the Transportation Security Administration (TSA) security lines at any airport. Simply watch the frustration build as a particular item is run through the scanner for a third time while a passenger is running late to board his flight. Security implementations are based on a sliding scale; one end of the scale is total security and total inconvenience, the other is total insecurity and complete ease of use. When we implement any security mechanism, it should be placed on the scale where the level of security and ease of use match the acceptable level of risk for the organization.

2. COMPUTERS ARE POWERFUL AND COMPLEX

Home computers have become storehouses of personal materials. Our computers now contain wedding videos, scanned family photos, music libraries, movie collections, and financial and medical records. Because computers contain such familiar objects, we have forgotten that computers are very powerful and complex devices. It wasn't that long ago that computers as powerful as our desktop

and laptop computers would have filled one or more very large rooms. In addition, today's computers present a "user-friendly" face to the world. Most people are unfamiliar with the way computers truly function and what goes on "behind the scenes." Things such as the Windows Registry, ports, and services are completely unknown to most users and poorly understood by many computer industry professionals. For example, many individuals still believe that a Windows login password protects data on a computer. On the contrary—someone can simply take the hard drive out of the computer, install it as a slave drive in another computer, or place it in a USB drive enclosure, and all the data will be readily accessible.

Computer Users Are Unsophisticated

Many computer users believe that because they are skilled at generating spreadsheets, word processing documents, and presentations, they know everything about computers. These "power users" have moved beyond application basics, but many still do not understand even basic security concepts. Many users will indiscriminately install software and visit questionable Web sites despite the fact that these actions could violate company policies. The "bad guys"—people who want to steal information from or wreak havoc on computers systems—have also identified the average user as a weak link in the security chain. As companies began investing more money in perimeter defenses, attackers look to the path of least resistance. They send malware as attachments to email, asking recipients to open the attachment. Despite being told not to open attachments from unknown senders or simply not to open attachments at all, employees consistently violate this policy, wreaking havoc on their networks. The "I Love You Virus" spread very rapidly in this manner. More recently, phishing scams have been very effective in convincing individuals to provide their personal online banking and credit-card information. Why would an attacker struggle to break through an organization's defenses when end users are more than willing to provide the keys to bank accounts? Addressing the threat caused by untrained and unwary end users is a significant part of any security program.

Computers Created Without a Thought to Security

During the development of personal computers (PCs), no thought was given to security. Early PCs were very simple affairs that had limited computing power and no keyboards and were programmed by flipping a series of switches. They were developed almost as curiosities. Even as they became more advanced and complex, all effort was focused on developing greater sophistication and capabilities; no one thought they would have security issues. We only have to look at some of the early computers, such as the Berkeley Enterprises Geniac, the Heathkit EC-1, or the MITS Altair 8800, to understand why security was not an issue back then.[2] The development of computers was focused on what they could do, not how they could be attacked.

As computers began to be interconnected, the driving force was providing the ability to share information, certainly not to protect it. Initially, the Internet was designed for military applications, but eventually it migrated to colleges and universities, the principal tenet of which is the sharing of knowledge.

3. CURRENT TREND IS TO SHARE, NOT PROTECT

Even now, despite the stories of compromised data, people still want to share their data with everyone. Web-based applications are making this easier to do than simply attaching a file to an email. Social networking sites such as Omemo provide the ability to share material: "Store your files online, share your stuff and browse what other users store in the world's largest multimedia library: The Omemo peer-to-peer virtual hard-drive."[3] In addition, many online data storage sites such as DropSend[4] and FilesAnywhere[5] provide the ability to share files. These sites can allow proprietary data to leave an organization by bypassing security mechanisms, exposing them to the possibility of unwanted review and distribution.

Data Accessible from Anywhere

As though employees' desire to share data is not enough of a threat to proprietary information, many business professionals want access to data from anywhere they work, on a variety of devices. To be productive, employees now request access to data and contact information on their laptops, desktops, home computers, and mobile devices. Therefore, IT departments must now provide the ability to sync data with numerous systems. And if the IT department can't or won't provide this capability, employees now have the power to take matters into their own hands by utilizing online services.

In addition to the previously mentioned online file sharing sites, there exist numerous online file storage sites (some sites offer both services). These storage

2. "Pop quiz: What was the first personal computer?" www.blinkenlights.com/pc.shtml (February 2, 2012).

4. www.dropsend.com (February 2, 2012).
5. www.filesanywhere.com (February 2, 2012).

sites are "springing up" everywhere, based on the desire to have access to data from absolutely everywhere. The latest operating systems from Microsoft and Apple support this concept on a home network level when they created Homegroups[6] and AirDrop, respectively. Homegroups allow users to share specific volumes or folders across a network, while AirDrop allows users to share files between Mac's, without using an established network.

"Looking for a fast way to share files with people nearby? With AirDrop, you can send files to anyone around you wirelessly—no Wi-Fi network required. And no complicated setup or special settings. Just click the AirDrop icon in the Finder sidebar, and your Mac automatically discovers other AirDrop users within about 30 feet of you. To share a file, simply drag it to someone's name. Once accepted, the fully encrypted file transfers directly to that person's Downloads folder."[7]

Employees always seem to want the same capabilities they have at home while in the workplace. This desire stems from the desire to work quickly and efficiently, with as few impediments in place as possible. Many computer users appreciate the simplicity with which they can access files while at home; they expect the same capabilities in the workplace.

Currently, the best known file storage site is Dropbox.[8] Currently, Dropbox provides 2 GB of free storage and software for Windows, Mac, Linux, and mobile devices, including iPhone, iPad, Blackberry and Android. This matches with their slogan, "Your files everywhere you are." However, you do not need to install the application on your computer; there is a web interface that allows you to upload new files and access stored files. From an accessibility perspective, this is truly amazing. From a security perspective, it is a little unnerving. Some security professionals will not consider this an issue because they can simply "blacklist" the Dropbox Web site and prevent users from installing software. However, if one thinks about this, what is to stop someone from storing material on one of these sites while using a home or library computer? Additionally, Dropbox is not the only "game in town." There are dozens of these sites; some of them are rather obscure, and new ones are created periodically. Table 1.1 identifies sites that have been identified as of this writing (and there are likely more in existence).

Some familiar tools also offer file storage capabilities. Google's free email service, Gmail is a great tool that provides a very robust service for free. What few people realize is that Gmail provides more than 7 GB of storage

that can also be used to store files, not just email. The shell extension, Gmail Drive[9] provides access to your Gmail storage by means of a "drive" on your desktop. Figure 1.1 shows the Gmail Drive login screen. This ability to easily transfer data outside the control of a company makes securing an organization's data that much more difficult. There is more to these sites than simply losing control of data. These are third-party sites and anything can happen. As an example in the summer of 2011, Dropbox had a security issue that allowed people to log in to any account without the use of a password. Another issue is that the longevity of these sites is not guaranteed. For example, Xdrive, a popular online storage service created in 1999 and purchased by AOL in 2005 (allegedly for US$30 million), shut down on January 12, 2009. What happens to the data that is on systems that are no longer in service?

9. http://www.viksoe.dk/gmail/ (February 22, 2012).

4. SECURITY ISN'T ABOUT HARDWARE AND SOFTWARE

Many businesses believe that if they purchase enough equipment, they can create a secure infrastructure. Firewalls, intrusion detection systems, antivirus programs, and two-factor authentication products are just some of the tools available to assist in protecting a network and its data. It is important to keep in mind that no product or combination of products will create a secure organization by itself. Security is a process; there is no tool that you can "set and forget." All security products are only as secure as the people who configure and maintain them. The purchasing and implementation of security products should be only a percentage of the security budget. The employees tasked with maintaining the security devices should be provided with enough time, training, and equipment to properly support the products. Unfortunately, in many organizations security activities take a back seat to support activities. Highly skilled security professionals are often tasked with help-desk requests such as resetting forgotten passwords, fixing jammed printers, and setting up new employee workstations.

The Bad Guys Are Very Sophisticated

At one time the computer hacker was portrayed as a lone teenager with poor social skills who would break into systems, often for nothing more than bragging rights. As ecommerce has evolved, however, so has the profile of the hacker.

Now that vast collections of credit-card numbers and intellectual property can be harvested, organized hacker groups like Anonymous have been formed to operate as businesses. A document released in 2008 spells it out clearly: "Cybercrime companies that work much like real-world companies are starting to appear and are steadily growing, thanks to the profits they turn. Forget individual hackers or groups of hackers with common goals. Hierarchical cybercrime organizations where each

cybercriminal has his or her own role and reward system is what you and your company should be worried about."[10]

State-sponsored hacking, while discussed in security circles for years, received mainstream attention when a Chinese "how-to" hacking video was identified and discussed in the media.[11]

Now that organizations are being attacked by highly motivated and skilled groups of hackers, creating a secure infrastructure is mandatory.

Management Sees Security as a Drain on the Bottom Line

For most organizations, the cost of creating a strong security posture is seen as a necessary evil, similar to purchasing insurance. Organizations don't want to spend the money on it, but the risks of not making the purchase outweigh the costs. Because of this attitude, it is extremely challenging to create a secure organization. The attitude is enforced because requests for security tools are often supported by documents providing the average cost of a security incident instead of showing more concrete benefits of a strong security posture. The problem is exacerbated by the fact that IT professionals speak a different language than management. IT professionals are generally focused on technology, period. Management is focused on revenue. Concepts such as profitability, asset depreciation, return on investment, realization, and total cost of ownership are the mainstays of management. These are alien concepts to most IT professionals.

Realistically speaking, though, it would be helpful if management would take steps to learn some fundamentals of information technology and IT professionals should take the initiative and learn some fundamental business concepts. Learning these concepts is beneficial to the organization because the technical infrastructure can then be implemented in a cost-effective manner, and they are beneficial from a career development perspective for IT professionals.

A Google search on "business skills for IT professionals" will identify numerous educational programs that might prove helpful. For those who do not have the time or the inclination to attend a class, some very useful materials can be found online. One such document provided by the Government Chief Information Office of New South Wales is *A Guide for Government Agencies Calculating Return on Security Investment.*[12] Though extremely technical, another often cited document is *Cost-Benefit Analysis for Network Intrusion Detection Systems*, by Huaqiang Wei, Deb Frinke, Olivia Carter, and Chris Ritter.[13]

Regardless of the approach that is taken, it is important to remember that any tangible cost savings or revenue generation should be utilized when requesting new security products, tools, or policies. Security professionals often overlook the value of keeping Web portals open for employees. A database that is used by a sales staff to enter contracts or purchases or check inventory will help generate more revenue if it has no downtime. A database that is not accessible or has been hacked is useless for generating revenue.

Strong security can be used to gain a competitive advantage in the marketplace. Having secured systems that are accessible 24 hours a day, seven days a week, means that an organization can reach and communicate with its clients and prospective clients more efficiently. An organization that becomes recognized as a good custodian of client records and information can incorporate its security record as part of its branding. This is no different than a car company being recognized for its safety record. In discussions of cars and safety, for example, Volvo is always the first manufacturer mentioned.[14]

What must be avoided is the "sky is falling" mentality. There are indeed numerous threats to a network, but we need to be realistic in allocating resources to protect against these threats. As of this writing, the National Vulnerability Database sponsored by the National Institute of Standards and Technology (NIST) lists 49,679 common vulnerabilities and exposures and publishes 14 new vulnerabilities per day.[15] In addition, the media is filled with stories of stolen laptops, credit-card numbers, and identities. The volume of threats to a network can be mind numbing. It is important to approach management with "probable threats" as opposed to "describable threats." Probable threats are those that are most likely to have an impact on your business and the ones most likely to get the attention of management.

Perhaps the best approach is to recognize that management, including the board of directors, is required to exhibit a duty of care in protecting their assets that is comparable to that of other organizations in their industry. When a security breach or incident occurs, being

able to demonstrate the high level of security within the organization can significantly reduce exposure to lawsuits, fines, and bad press.

The goal of any discussion with management is to convince them that in the highly technical and interconnected world we live in, having a secure network and infrastructure is a "nonnegotiable requirement of doing business."[16] An excellent resource for both IT professionals and executives that can provide insight into these issues is CERT's technical report, *Governing for Enterprise Security.*[17]

5. TEN STEPS TO BUILDING A SECURE ORGANIZATION

Having identified some of the challenges to building a secure organization, let's now look at 10 ways to successfully build a secure organization. The following steps will put a business in a robust security posture.

Evaluate the Risks and Threats

In attempting to build a secure organization, where should you start? One commonly held belief is that you should initially identify your assets and allocate security resources based on the value of each asset. Although this approach might prove effective, it can lead to some significant vulnerabilities. An infrastructure asset might not hold a high value, for example, but it should be protected with the same effort as a high-value asset. If not, it could be an entry point into your network and provide access to valuable data.

Another approach is to begin by evaluating the threats posed to your organization and your data.

Threats Based on the Infrastructure Model

The first place to start is to identify risks based on an organization's infrastructure model. What infrastructure is in place that is necessary to support the operational needs of the business? A small business that operates out of one office has reduced risks as opposed to an organization that operates out of numerous facilities, includes a mobile workforce utilizing a variety of handheld devices, and offers products or services through a Web-based interface. An organization that has a large number of telecommuters must take steps to protect its proprietary information that could potentially reside on personally owned computers outside company control. An organization that has widely dispersed and disparate systems will have more risk potential than a centrally located one that utilizes uniform systems.

Threats Based on the Business Itself

Are there any specific threats for your particular business? Have high-level executives been accused of inappropriate activities whereby stockholders or employees would have incentive to attack the business? Are there any individuals who have a vendetta against the company for real or imagined slights or accidents? Does the community have a history of antagonism against the organization? A risk management or security team should be asking these questions on a regular basis to evaluate the risks in real time. This part of the security process is often overlooked due to the focus on daily workload.

Threats Based on Industry

Businesses belonging to particular industries are targeted more frequently and more aggressively than those in other industries. Financial institutions and online retailers are targeted because "that's where the money is." Pharmaceutical manufacturers could be targeted to steal intellectual property, but they also could be targeted by special interest groups, such as those that do not believe in testing drugs on live animals or have spiritual beliefs opposing a particular product.

Identifying some of these threats requires active involvement in industry-specific trade groups in which businesses share information regarding recent attacks or threats they have identified.

Global Threats

Businesses are often so narrowly focused on their local sphere of influence that they forget that by having a network connected to the Internet, they are now connected to the rest of the world. If a piece of malware identified on the other side of the globe targets the identical software used in your organization, you can be sure that you will eventually be impacted by this malware. Additionally, if extremist groups in other countries are targeting your specific industry, you will also be targeted.

Once threats and risks are identified, you can take one of four steps:

- *Ignore the risk.* This is never an acceptable response. This is simply burying your head in the sand and hoping the problem will go away—the business equivalent of not wearing a helmet when riding a motorcycle.

16. "Why leaders should care about security" podcast transcript, October 17, 2006, Julia Allen and William Pollak, http://www.cert.org/podcast/transcripts/1leaders_care.pdf (February 22, 2012).
17. www.cert.org/archive/pdf/05tn023.pdf.

- *Accept the risk.* When the cost to remove the risk is greater than the risk itself, an organization will often decide to simply accept the risk. This is a viable option as long as the organization has spent the time required to evaluate the risk.
- *Transfer the risk.* Organizations with limited staff or other resources could decide to transfer the risk. One method of transferring the risk is to purchase specialized insurance targeted at a specific risk.
- *Mitigate the risk.* Most organizations mitigate risk by applying the appropriate resources to minimize the risks posed to their network and systems.

For organizations that would like to identify and quantify the risks to their network and information assets, CERT provides a free suite of tools to assist with the project. Operationally, Critical Threat, Asset, and Vulnerability Evaluation (OCTAVE) provides risk-based assessment for security assessments and planning.[18] There are three versions of OCTAVE: the original OCTAVE, designed for large organizations (more than 300 employees); OCTAVE-S (100 people or fewer); and OCTAVE-Allegro, which is a streamlined version of the tools and focuses specifically on information assets.

Another risk assessment tool that might prove helpful is the Risk Management Framework developed by Educause/Internet 2.[19] Targeted at institutions of higher learning, the approach could be applied to other industries. Another framework that might prove helpful was developed by the National Institute of Standards and Technology (NIST). This is also referred to as the Risk Management Framework (RMF) and includes six steps as part of the process.[20]

Tracking specific threats to specific operating systems, products, and applications can be time consuming. Visiting the National Vulnerability Database and manually searching for specific issues would not necessarily be an effective use of time. Fortunately, the Center for Education and Research in Information Assurance and Security (CERIAS) at Purdue University has a tool called Cassandra that can be configured to notify you of specific threats to your particular products and applications.[17]

Beware of Common Misconceptions

In addressing the security needs of an organization, it is common for professionals to succumb to some very common misconceptions. Perhaps the most common misconception is that the business is obscure, unsophisticated, or boring—simply not a target for malicious activity. Businesses must understand that any network that is connected to the Internet is a potential target, regardless of the type of business.

Attackers will attempt to gain access to a network and its systems for several reasons. The first reason is to look around to see what they can find. Regardless of the type of business, personnel information will more than likely be stored on one of the systems. This includes Social Security numbers and other personal information. This type of information is a target—always.

Another possibility is that the attacker will modify the information he or she finds or simply reconfigure the systems to behave abnormally. This type of attacker is not interested in financial gain; he is simply the technology version of teenagers who soaps windows, eggs cars, and covers property with toilet paper. He attacks because he finds it entertaining to do so. Additionally, these attackers could use the systems to store stolen "property" such as child pornography or credit-card numbers. If a system is not secure, attackers can store these types of materials on your system and gain access to them at their leisure.

The final possibility is that an attacker will use the hacked systems to mount attacks on other unprotected networks and systems. Computers can be used to mount denial-of-service (DoS) attacks, operate as "command and control systems" for a bot network, relay spam, or spread malicious software. To put it simply, no computer or network is immune from attack.

Another common misconception is that an organization is immune from problems caused by employees, essentially saying, "We trust all our employees, so we don't have to focus our energies on protecting our assets from them." Though this is common for small businesses in which the owners know everyone, it also occurs in larger organizations where companies believe that they only hire "professionals." It is important to remember that no matter how well job candidates present themselves, a business can never know everything about an employee's past. For this reason it is important for businesses to conduct preemployment background checks of all employees. Furthermore, it is important to conduct these background checks properly and completely.

Many employers trust this task to an online solution that promises to conduct a complete background check on an individual for a minimal fee. Many of these sites play on individuals' lack of understanding of how some of these online databases are generated. These sites might not have access to the records of all jurisdictions, since many jurisdictions either do not make their records available online or do not provide them to these

18. OCTAVE, www.cert.org/octave/ (February 22, 2012).
19. Risk Management Framework, https://wiki.internet2.edu/confluence/display/itsg2/Risk+Management+Framework. (February 22, 2012).
20. Risk Management Framework (RMF), http://csrc.nist.gov/groups/SMA/fisma/framework.html (March 4, 2012).

databases. In addition, many of the records are entered by minimum wage data-entry clerks whose accuracy is not always 100 percent.

Background checks should be conducted by organizations that have the resources at their disposal to get court records directly from the courthouses where the records are generated and stored. Some firms have a team of "runners" who visit the courthouses daily to pull records; others have a network of contacts who can visit the courts for them. Look for organizations that are active members of the National Association of Professional Background Screeners.[21] Members of this organization are committed to providing accurate and professional results. And perhaps more importantly, they can provide counseling regarding the proper approach to take as well as interpreting the results of a background check.

If your organization does not conduct background checks, there are several firms that might be of assistance: Accurate Background, Inc., of Lake Forest, California[22]; Credential Check, Inc., of Troy, Michigan[23]; and Validity Screening Solutions in Overland Park, Kansas.[24] The Web sites of these companies all provide informational resources to guide you in the process. (*Note:* For businesses outside the United States or for U.S. businesses with locations overseas, the process might be more difficult because privacy laws could prevent conducting a complete background check. The firms we've mentioned should be able to provide guidance regarding international privacy laws.)

Another misconception is that a preemployment background check is all that is needed. Some erroneously believe that once a person is employed, he or she is "safe" and can no longer pose a threat. However, people's lives and fortunes can change during the course of employment. Financial pressures can cause otherwise law-abiding citizens to take risks they never would have thought possible. Drug and alcohol dependency can alter people's behavior as well. For these and other reasons it is a good idea to do an additional background check when an employee is promoted to a position of higher responsibility and trust. If this new position involves handling financial responsibilities, the background check should also include a credit check.

Although these steps might sound intrusive, which is sometimes a reason cited not to conduct these types of checks, they can also be very beneficial to the employee as well as the employer. If a problem is identified during the check, the employer can often offer assistance to help the employee get through a tough time. Financial counseling and substance abuse counseling can often turn a potentially problematic employee into a very loyal and dedicated one.

Yet another common misconception involves information technology (IT) professionals. Many businesses pay their IT staff fairly high salaries because they understand that having a properly functioning technical infrastructure is important for the continued success of the company. Since the staff is adept at setting up and maintaining systems and networks, there is a general assumption that they know "everything there is to know about computers. It is important to recognize that although an individual might be very knowledgeable and technologically sophisticated, no one knows *everything* about computers. Because management does not understand technology, they are not in a very good position to judge a person's depth of knowledge and experience in the field. Decisions are often based on the certifications a person has achieved during his or her career. Although certifications can be used to determine a person's level of competency, too much weight is given to them. Many certifications require nothing more than some time and dedication to study and pass a certification test. Some training companies also offer boot camps that guarantee a person will pass the certification test. It is possible for people to become certified without having any real-world experience with the operating systems, applications, or hardware addressed by the certification. When judging a person's competency, look at his or her experience level and background first, and if the person has achieved certifications in addition to having significant real-world experience, the certification is probably a reflection of the employee's true capabilities.

The IT staff does a great deal to perpetuate the image that they know everything about computers. One of the reasons people get involved with the IT field in the first place is because they have an opportunity to try new things and overcome new challenges. This is why when an IT professional is asked if she knows how to do something, she will always respond "Yes." But in reality the real answer should be, "No, but I'll figure it out." Although they frequently can figure things out, when it comes to security we must keep in mind that it is a specialized area, and implementing a strong security posture requires significant training and experience.

Provide Security Training for IT Staff—Now and Forever

Just as implementing a robust, secure environment is a dynamic process, creating a highly skilled staff of security

professionals is also a dynamic process. It is important to keep in mind that even though an organization's technical infrastructure might not change that frequently, new vulnerabilities are being discovered and new attacks are being launched on a regular basis. In addition, very few organizations have a stagnant infrastructure; employees are constantly requesting new software, and more technologies are added in an effort to improve efficiencies. Each new addition likely adds additional security vulnerabilities.

It is important for the IT staff to be prepared to identify and respond to new threats and vulnerabilities. It is recommended that those interested in gaining a deep security understanding start with a vendor-neutral program. A vendor-neutral program is one that focuses on concepts rather than specific products. The SANS (SysAdmin, Audit, Network, Security) Institute offers two introductory programs: Intro to Information Security (Security 301),[25] a five-day class designed for people just starting out in the security field, and the SANS Security Essentials Bootcamp (Security 401),[26] a six-day class designed for people with some security experience. Each class is also available as a self-study program, and each can be used to prepare for a specific certification.

Another option is to start with a program that follows the CompTia Security + certification requirements, such as the Global Knowledge Essentials of Information Security.[27] Some colleges offer similar programs.

Once a person has a good fundamental background in security, he should then undergo vendor-specific training to apply the concepts learned to specific applications and security devices utilized in the work environment.

A great resource for keeping up with current trends in security is to become actively involved in a security-related trade organization. The key concept here is *actively involved*. Many professionals join organizations so that they can add an item to the "professional affiliations" section of their résumé. Becoming actively involved means attending meetings on a regular basis and serving on a committee or in a position on the executive board. Although this seems like a daunting time commitment, the benefit is that the professional develops a network of resources that can be available to provide insight, serve as a sounding board, or provide assistance when a problem arises. Participating in these associations is a very cost-effective way to get up to speed with current security trends and issues. Here are some organizations[28] that can prove helpful:

- ASIS International, the largest security-related organization in the world, focuses primarily on physical security but has more recently started addressing computer security as well.
- ISACA, formerly the Information Systems Audit and Control Association.
- High Technology Crime Investigation Association (HTCIA).
- Information Systems Security Association (ISSA).
- InfraGard, a joint public and private organization sponsored by the Federal Bureau of Investigation (FBI).

In addition to monthly meetings, many local chapters of these organizations sponsor regional conferences that are usually very reasonably priced and attract nationally recognized experts.

Arguably one of the best ways to determine whether an employee has a strong grasp of information security concepts is if she can achieve the Certified Information Systems Security Professional (CISSP) certification. Candidates for this certification are tested on their understanding of the following 10 knowledge domains:

- Access control
- Application security
- Business continuity and disaster recovery planning
- Cryptography
- Information security and risk management
- Legal regulations, compliance, and investigations
- Operations security
- Physical (environmental) security
- Security architecture and design
- Telecommunications and network security

What makes this certification so valuable is that the candidate must have a minimum of five years of professional experience in the information security field or four years of experience and a college degree. To maintain certification, a certified individual is required to attend 120 hours of continuing professional education during the three-year certification cycle. This ensures that those holding the CISSP credential are staying up to date with current trends in security. The CISSP certification is maintained by internet systems consortium (ISC).[29]

Think "Outside the Box"

For most businesses, the threat to their intellectual assets and technical infrastructure comes from the "bad guys"

25. https://www.sans.org/security-training/intro-information-security-106-mid.

sitting outside their organizations, trying to break in. These organizations establish strong perimeter defenses, essentially "boxing in" their assets. However, internal employees have access to proprietary information to do their jobs, and they often disseminate this information to areas where it is no longer under the control of the employer. This dissemination of data is generally not performed with any malicious intent, but simply for employees to have access to data so that they can perform their job responsibilities more efficiently. However, this becomes a problem when an employee leaves and the organization takes no steps to collect or control their proprietary information in the possession of their now ex-employee.

One of the most overlooked threats to intellectual property is the innocuous and now ubiquitous USB Flash drive. These devices, the size of a tube of lipstick, are the modern-day floppy disk in terms of portable data storage. They are a very convenient way to transfer data between computers. But the difference between these devices and a floppy disk is that USB Flash drives can store a very large amount of data. A 16 GB USB Flash drive has the same storage capacity as more than 10,000 floppy disks! As of this writing, a 16 GB USB Flash drive can be purchased for less than $15. Businesses should keep in mind that as time goes by, the capacity of these devices will increase and the price will decrease, making them very attractive to employees.

These devices are not the only threat to data. Because other devices can be connected to the computer through the USB port, digital cameras, MP3 players, and external hard drives can now be used to remove data from a computer and the network to which it is connected. Most people would recognize that external hard drives pose a threat, but they would not recognize other devices as a threat. Cameras and music players are designed to store images and music, but to a computer they are simply additional mass storage devices. It is difficult for people to understand that an iPod can carry word processing documents, databases, and spreadsheets as well as music. Fortunately, Microsoft Windows tracks the devices that are connected to a system in a Registry key, HKEY_Local_Machine\System\ControlSet00x\Enum\USBStor. It might prove interesting to look in this key on your own computer to see what types of devices have been connected. Figure 1.2 shows a wide array of devices that have been connected to a system that includes USB Flash drives, a digital camera, and several external hard drives.

Windows Vista has an additional key that tracks connected devices: HKEY_Local_Machine\Software\Microsoft\Windows Portable Devices\Devices.[30] (*Note:* Analyzing

30. http://windowsir.blogspot.com/2008/06/portable-devices-on-vista.html (February 29, 2012).

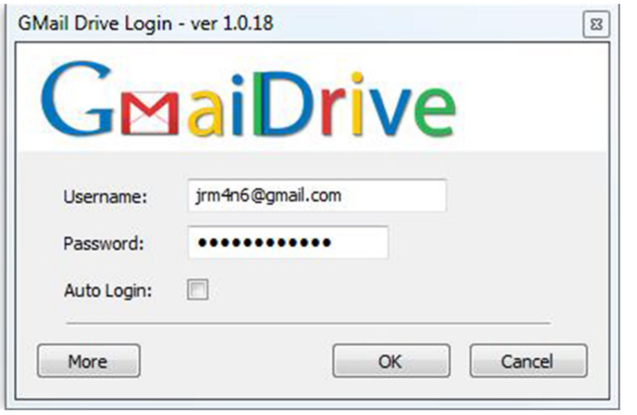

FIGURE 1.2 Gmail Drive login screen.

the Registry is a great way to investigate the activities of computer users. For many, however, the Registry is tough to navigate and interpret. If you are interested in understanding more about the Registry, you might want to download and play with Harlan Carvey's RegRipper.[31])

Another threat to information that carries data outside the walls of the organization is the plethora of handheld devices currently in use. Many of these devices have the ability to send and receive email as well as create, store, and transmit word processing, spreadsheet, and PDF files. Though most employers will not purchase these devices for their employees, they are more than happy to allow their employees to sync their personally owned devices with their corporate computers. Client contact information, business plans, and other materials can easily be copied from a system. Some businesses feel that they have this threat under control because they provide their employees with corporate-owned devices and they can collect these devices when employees leave their employment. The only problem with this attitude is that employees can easily copy data from the devices to their home computers before the devices are returned.

Because of the threat of portable data storage devices and handheld devices, it is important for an organization to establish policies outlining the acceptable use of these devices as well as implement an enterprise-grade solution to control how, when, or if data can be copied to them. Filling all USB ports with epoxy is a cheap solution, but it is not really effective. Fortunately, there are several products that can protect against this type of data leak. DeviceWall from Frontrange Solutions[32] and GFI Endpoint Security[33] are two popular ones.

DOXing

With the interest and ability to store data on third-party systems, it becomes increasingly necessary for the security professional to make "thinking outside the box" a part of their set of skills. While it does not seem that a security professional should be concerned with data being stored on systems other than their own, the fact that business critical and confidential materials are stored on third-party systems means that the success or profitability of a business requires that this information be secured.

In addition to data leaving an organization on thumb drives or to an external storage site, seemingly innocuous data can be collected from a variety of sources and can be used in a negative manner against an individual or organization. This process is called DOXing and is defined by the ProHackingTricks:

Doxing is a way of tracing someone or getting information about an individual using sources on the internet and social engineering techniques. Its term was derived from—Documents—as a matter of fact it's the retrieval of Documents on a person or an organization.[34]

DOXing is essentially high-tech dumpster diving, where information is gathered from the Internet as opposed to a waste bin. Initially developed by the hacker group Anonymous to harass law enforcement, the tactic was also utilized by the Occupy Wall Street protesters. This technique is possible because individuals and organizations do not understand the significance of data posted on social networking sites, blogs, corporate Web sites, and other online repositories. A single piece of information posted on a Web site may not in and of itself have significance, but when combined with materials collected from a variety of sites, that small piece of information may help fill in a complete (and possibly uncomplimentary) picture of a person or business. While this process has been targeted at law enforcement, it is just a matter of time before it will be used against executives and corporations. Being aware of this threat and educating others are now a part of the security process.

Train Employees: Develop a Culture of Security

One of the greatest security assets is a business's own employees, but only if they have been properly trained to comply with security policies and to identify potential security problems.

Many employees don't understand the significance of various security policies and implementations. As mentioned previously, they consider these policies nothing more than an inconvenience. Gaining the support and allegiance of employees takes time, but it is time well spent. Begin by carefully explaining the reasons behind any security implementation. One of the reasons could be ensuring employee productivity, but focus primarily on the security issues. File sharing using LimeWire and Shareazza might keep employees away from work, but they can also open up holes in a firewall. Downloading and installing unapproved software can install malicious software that can infect user systems, causing their computers to function slowly or not at all. While most employees understand that opening unknown or unexpected email attachments can lead to a malware infection, most are unaware of the advanced capabilities of recent malicious code. "Advanced Persistent Threat" or the ability for a system to remain infected despite the diligent use antivirus programs has become a major problem. Employees now need to understand that indiscriminate Web surfing can result in "drive-by" installs of malware.

Perhaps the most direct way to gain employee support is to let employees know that the money needed to respond to attacks and fix problems initiated by users is money that is then not available for raises and promotions. Letting employees know that they now have some "skin in the game" is one way to get them involved in security efforts. If a budget is set aside for responding to security problems and employees help stay well within the budget, the difference between the money spent and the actual budget could be divided among employees as a bonus. Not only would employees be more likely to speak up if they noticed network or system slowdowns, they would probably be more likely to confront strangers wandering through the facility.

Another mechanism that can be used to gain security allies is to provide advice regarding the proper security mechanisms for securing home computers. Although some might not see this as directly benefiting the company, keep in mind that many employees have corporate data on their home computers. This advice can come from periodic, live presentations (offer refreshments and attendance will be higher) or from a periodic newsletter that is either mailed or emailed to employees' personal addresses.

The goal of these activities is to encourage employees to approach management or the security team voluntarily. When this begins to happen on a regular basis, you will have expanded the capabilities of your security team and created a much more secure organization.

The security expert Roberta Bragg used to tell a story of one of her clients who took this concept to a high level. The client provided the company mail clerk with a WiFi hotspot detector and promised him a free steak dinner for every unauthorized wireless access point he

34. http://prohackingtricks.blogspot.com/2011/06/doxing-way-of-tracing-anonymous-people.html (February 29, 2012).

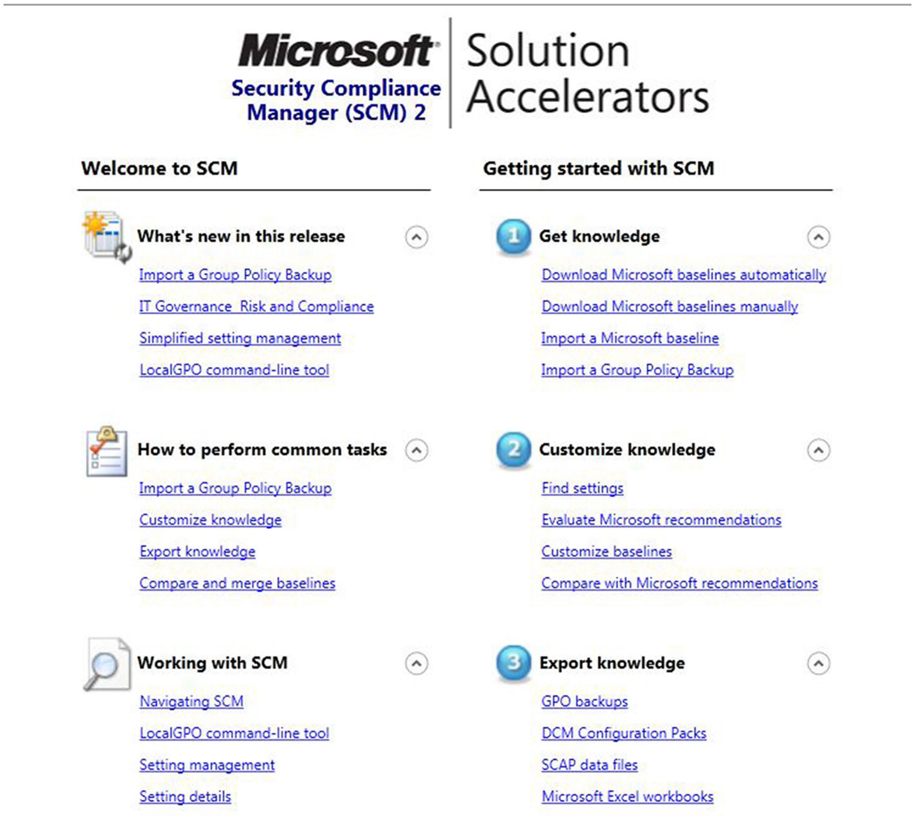

FIGURE 1.3 Microsoft Security Compliance Manager.

could find on the premises. The mail clerk was very happy to have the opportunity to earn three free steak dinners.

Identify and Utilize Built-in Security Features of the Operating System and Applications

Many organizations and systems administrators state that they cannot create a secure organization because they have limited resources and simply do not have the funds to purchase robust security tools. This is a ridiculous approach to security because all operating systems and many applications include security mechanisms that require no organizational resources other than time to identify and configure these tools. For Microsoft Windows operating systems, a terrific resource is the online Microsoft TechNet Library.[35] Under the Solutions Accelerators link you can find security resources for all recent Microsoft products. An example of the tools available is the Microsoft Security Compliance Manager. Figure 1.3 shows the initial screen for this product.

TechNet is a great resource and can provide insight into managing numerous security issues, from Microsoft Office 2007 to security risk management. These documents can assist in implementing the built-in security features of Microsoft Windows products. Assistance is needed in identifying many of these capabilities because they are often hidden from view and turned off by default.

One of the biggest concerns in an organization today is data leaks, which are ways that confidential information can leave an organization despite robust perimeter security. As mentioned previously, USB Flash drives are one cause of data leaks; another is the recovery of data found in the unallocated clusters of a computer's hard drive. Unallocated clusters, or *free space*, as it is commonly called, is the area of a hard drive where the operating system and applications dump their artifacts or residual data. Although this data is not viewable through the graphical user interface, the data can easily be identified (and sometimes recovered) using a hex editor such as WinHex[36] or one of the several commercially available computer forensics programs. Figure 1.4 shows the contents of unallocated clusters being displayed by EnCase Forensic.

35. Microsoft TechNet Library, http://technet.microsoft.com.

36. WinHex, www.x-ways.net/winhex/index-m.html.

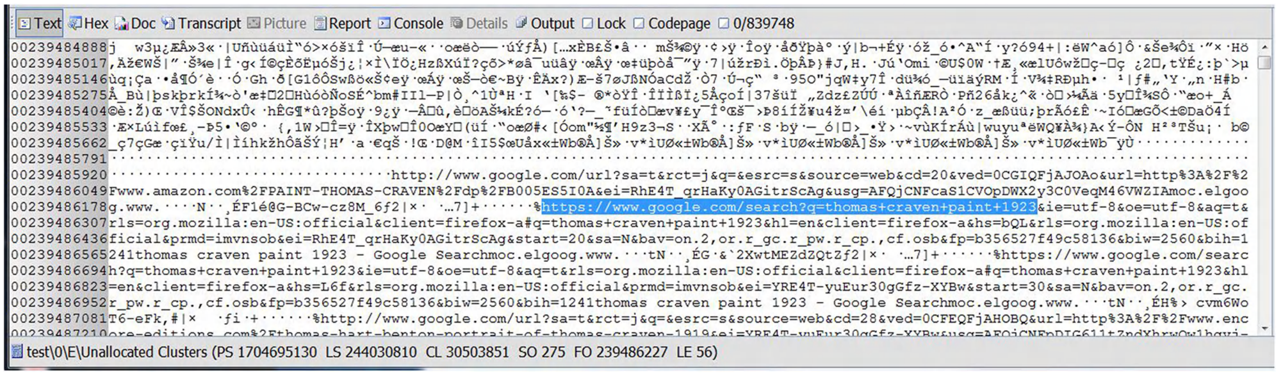

FIGURE 1.4 A view of unallocated clusters showing a Google query.

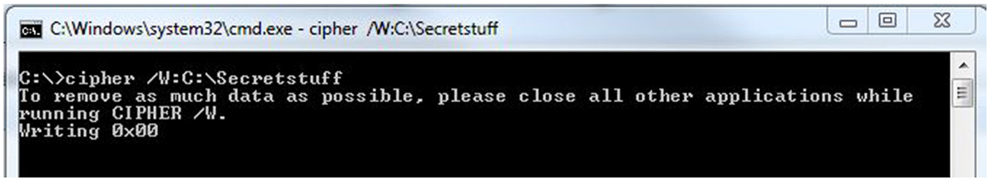

FIGURE 1.5 Cipher wiping a folder called Secretstuff.

Should a computer be stolen or donated, it is very possible that someone could access the data located in unallocated clusters. For this reason, many people struggle to find an appropriate "disk-scrubbing" utility. Many such commercial utilities exist, but there is one built into Microsoft Windows operating systems. The command-line program cipher.exe is designed to display or alter the encryption of directories (files) stored on new technology file system (NTFS) partitions. Few people even know about this command; even fewer are familiar with the */w* switch. Here is a description of the switch from the program's Help file:

Removes data from available unused disk space on the entire volume. If this option is chosen, all other options are ignored. The directory specified can be anywhere in a local volume. If it is a mount point or points to a directory in another volume, the data on that volume will be removed.

To use Cipher, click **Start** | and type **cmd** in the **"Search Programs and Files"** Bod. When the cmd.exe window opens, type **cipher /w:*folder*,** where *folder* is any folder in the volume that you want to clean, and then press **Enter**. Figure 1.5 shows Cipher wiping a folder.

For more on secure file deletion issues, see the author's white paper in the SANS reading room, "Secure file deletion: Fact or fiction?"[37]

37. "Secure file deletion: Fact or fiction?" www.sans.org/reading_room/whitepapers/incident/631.php (February 29, 2012).

Another source of data leaks is the personal and editing information that can be associated with Microsoft Office files. In Microsoft Word 2003 you can configure the application to remove personal information on save and to warn you when you are about to print, share, or send a document containing tracked changes or comments.

To access this feature, within Word click **Tools** | **Options** and then click the **Security** tab. Toward the bottom of the security window you will notice the two options described previously. Simply select the options you want to use. Figure 1.9 shows these options. Microsoft Office 2007 made this tool more robust and more accessible. A separate tool called Document Inspector can be accessed by clicking the **Microsoft Office** button, pointing to **Prepare Document**, then clicking **Inspect Document**. Then select the items you want to remove.

In Microsoft Office 2010, click on **File, Info,** and **Check for Issues,** to open the "Document Inspector" Window.

Implementing a strong security posture often begins by making the login process more robust. This includes increasing the complexity of the login password. All passwords can be cracked, given enough time and resources, but the more difficult you make cracking a password, the greater the possibility the asset the password protects will stay protected.

All operating systems have some mechanism to increase the complexity of passwords. In Microsoft Windows 7 the preceeding can be accomplished by:

1. Open Local Security Policy by clicking the Start button, typing secpol.msc into the Search box, and

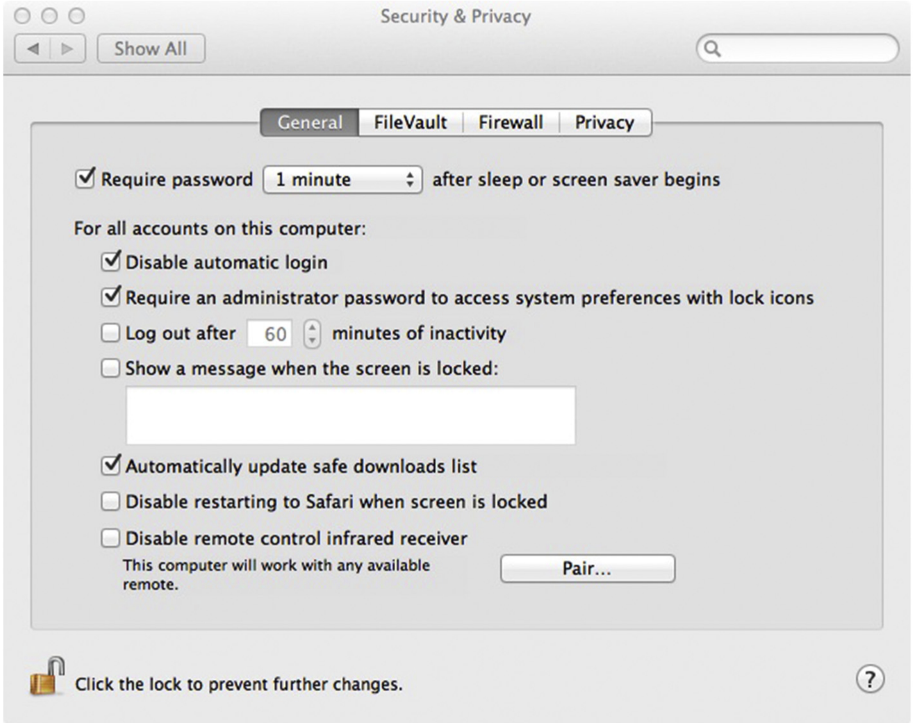

FIGURE 1.6 Security options for Mac OS X Lion.

then clicking secpol. If you are prompted for an administrator password or confirmation, type the password or provide confirmation.

2. In the Navigation pane, double-click Account Policies, and then click Password Policy.
3. Double-click the item in the Policy list that you want to change.[38]

In the right-hand panel you can enable password complexity. Once this is enabled, passwords must contain at least three of the four following password groups[36]:

- English uppercase characters (A through Z)
- English lowercase characters (a through z)
- Numerals (0 through 9)
- Nonalphabetic characters (such as !, $, #, %)

It is important to recognize that all operating systems have embedded tools to assist with security. They often require a little research to find, but the time spent in identifying them is less than the money spent on purchasing additional security products or recovering from a security breach.

Though not yet used by many corporations, Mac OS X has some very robust security features, including FileVault, which provides the ability to create an encrypted disk, including external drives. Figure 1.6 shows the security options for Mac OS X Lion.

Monitor Systems

Even with the most robust security tools in place, it is important to monitor your systems. All security products are manmade and can fail or be compromised. As with any other aspect of technology, one should never rely on simply one product or tool. Enabling logging on your systems is one way to put your organization in a position to identify problem areas. The problem is, what should be logged? There are some security standards that can help with this determination. One of these standards is the Payment Card Industry Data Security Standard (PCI DSS).[39] Requirement 10 of the PCI DSS states that organizations must “track and monitor access to network resources and cardholder data.” If you simply substitute *confidential information* for the phrase *cardholder data*, this requirement is an excellent approach to a log management program. Requirement 10 is reproduced here:

Logging mechanisms and the ability to track user activities are critical. The presence of logs in all environments allows thorough

38. http://windows.microsoft.com/en-US/windows-vista/Change-password-policy-settings (February 29, 2012).

39. PCI DSS, www.pcisecuritystandards.org.

tracking and analysis if something does go wrong. Determining the cause of a compromise is very difficult without system activity logs:

1. Establish a process for linking all access to system components (especially access done with administrative privileges such as root) to each individual user.
2. Implement automated audit trails for all system components to reconstruct the following events:
   - All individual user accesses to cardholder data
   - All actions taken by any individual with root or administrative privileges
   - Access to all audit trails
   - Invalid logical access attempts
   - Use of identification and authentication mechanisms
   - Initialization of the audit logs
   - Creation and deletion of system-level objects
3. Record at least the following audit trail entries for all system components for each event:
   - User identification
   - Type of event
   - Date and time
   - Success or failure indication
   - Origination of event
   - Identity or name of affected data, system component, or resource
4. Synchronize all critical system clocks and times.
5. Secure audit trails so that they cannot be altered:
   - Limit viewing of audit trails to those with a job-related need.
   - Protect audit trail files from unauthorized modifications.
   - Promptly back up audit trail files to a centralized log server or media that is difficult to alter.
   - Copy logs for wireless networks onto a log server on the internal LAN.
   - Use file integrity monitoring and change detection software on logs to ensure that existing log data cannot be changed without generating alerts (although new data being added should not cause an alert).
6. Review logs for all system components at least daily. Log reviews must include those servers that perform security functions like intrusion detection system (IDS) and authentication, authorization, and accounting protocol (AAA) servers (for example, RADIUS).

   Note: Log harvesting, parsing, and alerting tools may be used to achieve compliance.
7. Retain audit trail history for at least one year, with a minimum of three months online availability.

Item 6 looks a little overwhelming, since few organizations have the time to manually review log files. Fortunately, there are tools that will collect and parse log files from a variety of sources. All these tools have the ability to notify individuals of a particular event. One simple tool is the Kiwi Syslog Server[40] for Microsoft Windows. Figure 1.7 shows the configuration screen for setting up email alerts in Kiwi.

Additional log parsing tools include Microsoft's Log Parser[41] and, for Unix, Swatch.[42] Commercial tools include ArcSight Logger,[43] GFI EventsManager,[44] and LogRhythm.[45]

An even more detailed approach to monitoring your systems is to install a packet-capturing tool on your network so that you can analyze and capture traffic in real time. One tool that can be very helpful is Wireshark, which is "an award-winning network protocol analyzer developed by an international team of networking experts."[46] Wireshark is based on the original packet capture tool, Ethereal. Analyzing network traffic is not a trivial task and requires some training, but it is perhaps the most accurate way to determine what is happening on your network. Figure 1.8 shows Wireshark monitoring the traffic on a wireless interface.

Hire a Third Party to Audit Security

Regardless of how talented your staff is, there is always the possibility that they overlooked something or inadvertently misconfigured a device or setting. For this reason it is very important to bring in an extra set of "eyes, ears, and hands" to review your organization's security posture.

Although some IT professionals will become paranoid having a third party review their work, intelligent staff members will recognize that a security review by outsiders can be a great learning opportunity. The advantage of having a third party review your systems is that the outsiders have experience reviewing a wide range of systems, applications, and devices in a variety of industries. They will know what works well and what might work but cause problems in the future. They are also more likely to be up to speed on new vulnerabilities and the latest product updates. Why? Because this is all they do.

They are not encumbered by administrative duties, internal politics, and help desk requests. They will be more objective than in-house staff, and they will be in a position to make recommendations after their analysis.

The third-party analysis should involve a two-pronged approach: They should identify how the network appears to attackers and how secure the system is, should

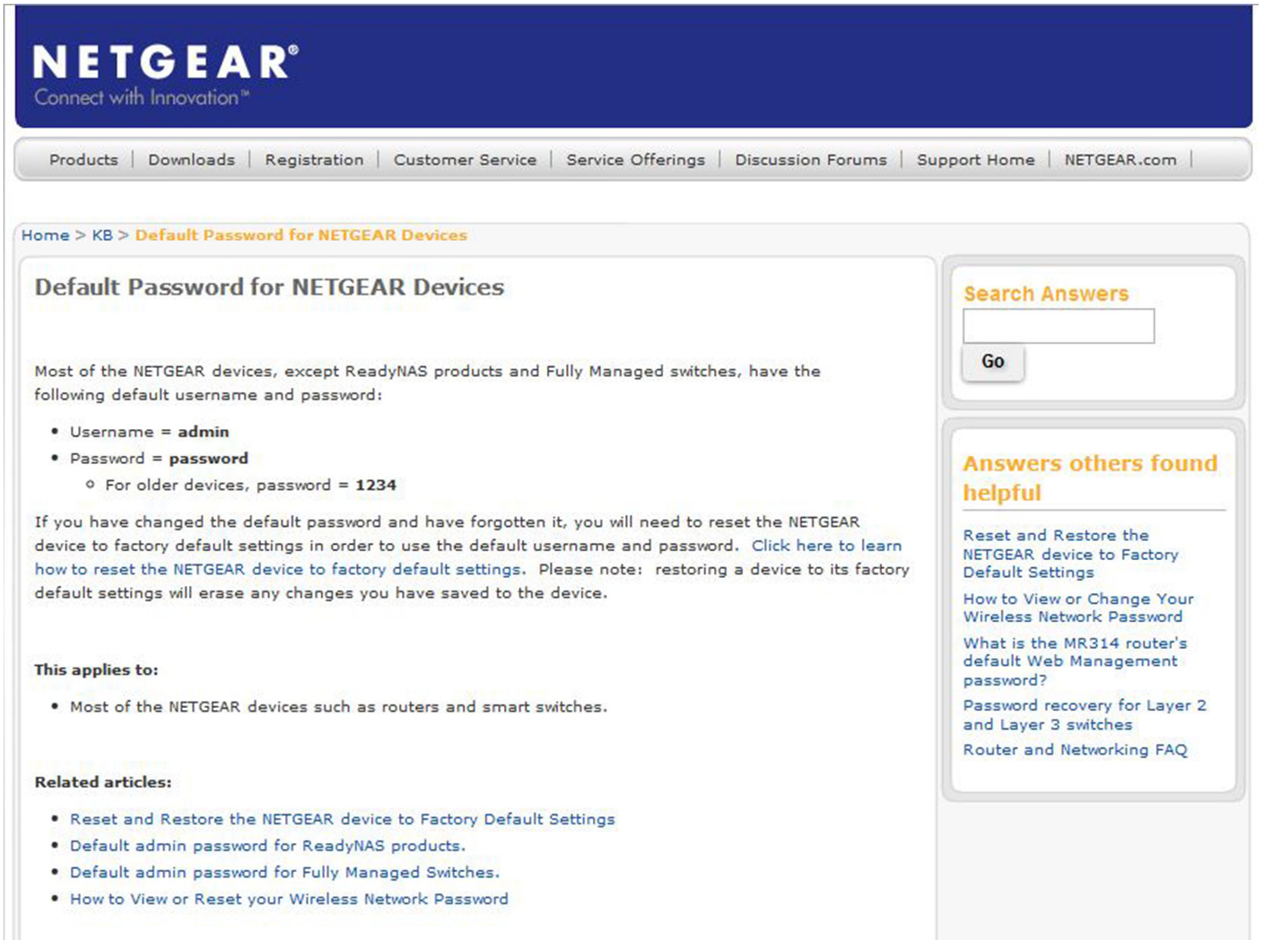

FIGURE 1.9 Default username and password for Netgear devices.

attackers make it past the perimeter defenses. You don't want to have "Tootsie Pop security"—a hard crunchy shell with a soft center. The external review, often called a *penetration test*, can be accomplished in several ways; the first is a *no knowledge* approach, whereby the consultants are provided with absolutely no information regarding the network and systems prior to their analysis. Although this is a very realistic approach, it can be time consuming and very expensive. Using this approach, consultants must use publicly available information to start enumerating systems for testing. This is a realistic approach, but a *partial knowledge* analysis is more efficient and less expensive. If provided with a network topology diagram and a list of registered IP addresses, the third-party reviewers can complete the review faster and the results can be addressed in a much more timely fashion. Once the penetration test is complete, a review of the internal network can be initiated. The audit of the internal network will identify open shares, unpatched systems, open ports, weak passwords, rogue systems, and many other issues.

Don't Forget the Basics

Many organizations spend a great deal of time and money addressing perimeter defenses and overlook some fundamental security mechanisms, as described here.

Change Default Account Passwords

Nearly all network devices come preconfigured with a password/username combination. This combination is included with the setup materials and is documented in numerous locations. Very often these devices are the gateways to the Internet or other internal networks. If these default passwords are not changed upon configuration, it becomes a trivial matter for an attacker to get into these systems. Hackers can find password lists on the Internet,[47] and vendors include default passwords in their online manuals. For example, Figure 1.9 shows the default username and password for Netgear devices.

Use Robust Passwords

With the increased processing power of our computers and password-cracking software such as the Passware products[48] and AccessData's Password Recovery Toolkit,[49] cracking passwords is fairly simple and straightforward. For this reason it is extremely important to create robust passwords. Complex passwords are hard for users to remember, though, so it is a challenge to create passwords that can be remembered without writing them down. One solution is to use the first letter of each word in a phrase, such as "**I** **l**ike **t**o **e**at **i**mported **c**heese **f**rom **H**olland." This becomes *IlteicfH*, which is an eight-character password using upper- and lowercase letters. This can be made even more complex by substituting an exclamation point for the letter *I* and substituting the number 3 for the letter *e*, so that the password becomes*!lt3icfH*. This is a fairly robust password that can be remembered easily.

Close Unnecessary Ports

Ports on a computer are logical access points for communication over a network. Knowing what ports are open on your computers will allow you to understand the types of access points that exist. The well-known port numbers are 0 through 1023. Some easily recognized ports and what they are used for are listed here:

- Port 21: FTP
- Port 23: Telnet
- Port 25: SMTP
- Port 53: DNS
- Port 80: HTTP
- Port 110: POP
- Port 119: NNTP

Since open ports that are not needed can be an entrance into your systems, and open ports that are open unexpectedly could be a sign of malicious software, identifying open ports is an important security process. There are several tools that will allow you to identify open ports. The built-in command-line tool *netstat* will allow you to identify open ports and process IDs by using the following switches:

– *a* Displays all connections and listening ports
– *n* Displays addresses and port numbers in numerical form
– *o* Displays the owning process ID associated with each connection

(*Note:* In Unix, netstat is also available but utilizes the following switches: –*atvp.*)

Other tools that can prove helpful are CurrPorts,[50] a graphical user interface (GUI) tool that allows you to export the results in delimited format, and TCPView[51] is a tool provided by Microsoft. Sample results are shown in Figure 1.10.

49. Password Recovery Toolkit, http://accessdata.com/products/computer-forensics/decryption.
50. CurrPorts, http://www.nirsoft.net/utils/cports.html.
51. TCPView, http://technet.microsoft.com/en-us/sysinternals/bb897437.

Patch, Patch, Patch

Nearly all operating systems have a mechanism for automatically checking for updates. This notification system should be turned on. Although there is some debate as to whether updates should be installed automatically, systems administrators should at least be notified of updates. They might not want to have them installed automatically, since patches and updates have been known to cause more problems than they solve. However, administrators should not wait too long before installing updates because this can unnecessarily expose systems to attack. A simple tool that can help keep track of system updates is the Microsoft Baseline Security Analyzer,[52] which also will examine other fundamental security configurations.

Use Administrator Accounts for Administrative Tasks

A common security vulnerability is created when systems administrators conduct administrative or personal tasks while logged into their computers with administrator rights. Tasks such as checking email, surfing the Internet, and testing questionable software can expose the computer to malicious software. This means that the malicious software can run with administrator privileges, which can create serious problems. Administrators should log into their systems using a standard user account to prevent malicious software from gaining control of their computers.

Restrict Physical Access

With a focus on technology, it is often easy to overlook nontechnical security mechanisms. If an intruder can gain physical access to a server or other infrastructure asset, the intruder will own the organization. Critical systems should be kept in secure areas. A secure area is one that provides the ability to control access to only those who need access to the systems as part of their job responsibilities. A room that is kept locked using a key that is only provided to the systems administrator, with the only duplicate stored in a safe in the office manager's office, is a good start. The room should not have any windows that can open. In addition, the room should have no labels or signs identifying it as a server room or network operations center. The equipment should not be stored in a closet where other employees, custodians, or contractors can gain access. The validity of your security mechanisms should be reviewed during a third-party vulnerability assessment.

52. Microsoft Baseline Security Analyzer, http://technet.microsoft.com/en-us/security/cc184923.

Don't Forget Paper!

With the advent of advanced technology, people have forgotten how information was stolen in the past—on paper. Managing paper documents is fairly straightforward. Locking file cabinets should be used—and locked consistently. Extra copies of proprietary documents, document drafts, and expired internal communications are some of the materials that should be shredded. A policy should be created to tell employees what they should and should not do with printed documents. The following example of the theft of trade secrets underscores the importance of protecting paper documents:

A company surveillance camera caught Coca-Cola employee Joya Williams at her desk looking through files and "stuffing documents into bags," Nahmias and FBI officials said. Then in June, an undercover FBI agent met at the Atlanta airport with another of the defendants, handing him $30,000 in a yellow Girl Scout Cookie box in exchange for an Armani bag containing confidential Coca-Cola documents and a sample of a product the company was developing, officials said.[53]

The steps to achieving security mentioned in this chapter are only the beginning. They should provide some insight into where to start building a secure organization.

Finally, let's briefly look at the process of building and assessing the security controls in organizational information systems including: the activities carried out by organizations and assessors to prepare for security control assessments; the development of security assessment plans; the conduct of security control assessments and the analysis, documentation, and reporting of assessment results; and postassessment report analysis and follow-on activities carried out by organizations.

6. PREPARING FOR THE BUILDING OF SECURITY CONTROL ASSESSMENTS

Conducting security control assessments in today's complex environment of sophisticated information technology infrastructures and high-visibility, mission-critical applications can be difficult, challenging, and resource-intensive. Success requires the cooperation and collaboration among all parties having a vested interest in the organization's information security posture, including information system owners, common control providers, authorizing officials, chief information officers, senior information security officers, and chief executive officers/heads of departments. Establishing an appropriate set of expectations before, during, and

53. Accused in theft of Coke secrets," *The Washington Post*, July 26, 2006, www.washingtonpost.com/wp-dyn/content/article/2006/07/05/AR2006070501717.html (February 29, 2012).

after the assessment is paramount to achieving an acceptable outcome—that is, producing information necessary to help the authorizing official make a credible, risk-based decision on whether to place the information system into operation or continue its operation.

Thorough preparation by the organization and the assessors is an important aspect of conducting effective security control assessments. Preparatory activities address a range of issues relating to the cost, schedule, and performance of the assessment (see checklist: "An Agenda for Action for Preparatory Activities").

7. SUMMARY

In preparation for the assessment of security controls, this chapter covered how necessary background information is assembled and made available to the assessors or assessment team in order to build a secure organization. To the extent necessary to support the specific assessment, the organization identifies and arranges access to:

- Elements of the organization responsible for developing, documenting, disseminating, reviewing, and updating

An Agenda for Action for Preparatory Activities

From the organizational perspective, preparing for the building of a security control assessment includes the following key activities (check all tasks completed):

_____**1.** Ensuring that appropriate policies covering security control assessments are in place and understood by all affected organizational elements.

_____**2.** Ensuring that all steps in the Risk Management Framework (RMF) prior to the security control assessment step have been successfully completed and received appropriate management oversight.

_____**3.** Ensuring that security controls identified as common controls (and the common portion of hybrid controls) have been assigned to appropriate organizational entities (common control providers) for development and implementation.

_____**4.** Establishing the objective and scope of the security control assessment (the purpose of the assessment and what is being assessed).

_____**5.** Notifying key organizational officials of the impending security control assessment and allocating necessary resources to carry out the assessment.

_____**6.** Establishing appropriate communication channels among organizational officials having an interest in the security control assessment.

_____**7.** Establishing time frames for completing the security control assessment and key milestone decision points required by the organization to effectively manage the assessment.

_____**8.** Identifying and selecting a competent assessor/assessment team that will be responsible for conducting the security control assessment, considering issues of assessor independence.

_____**9.** Collecting artifacts to provide to the assessor/assessment team (policies, procedures, plans, specifications, designs, records, administrator/operator manuals, information system documentation, interconnection agreements, previous assessment results).

_____**10.** Establishing a mechanism between the organization and the assessor and/or assessment team to minimize ambiguities or misunderstandings about security control implementation or security control weaknesses/deficiencies identified during the assessment.

Security control assessors/assessment teams begin preparing for the assessment by:

_____**11.** Obtaining a general understanding of the organization's operations (including mission, functions, and business processes) and how the information system that is the subject of the security control assessment supports those organizational operations.

_____**12.** Obtaining an understanding of the structure of the information system (system architecture).

_____**13.** Identifying the organizational entities responsible for the development and implementation of the common controls (or the common portion of hybrid controls) supporting the information system.

_____**14.** Establishing appropriate organizational points of contact needed to carry out the security control assessment.

_____**15.** Obtaining artifacts needed for the security control assessment (policies, procedures, plans, specifications, designs, records, administrator/operator manuals, information system documentation, interconnection agreements, previous assessment results).

_____**16.** Obtaining previous assessment results that may be appropriately reused for the security control assessment (reports, audits, vulnerability scans, physical security inspections, prior assessments, developmental testing and evaluation, vendor flaw remediation activities, International Organization for Standardization/ International Electrotechnical Commission (ISO/IEC) 15408 (Common Criteria) evaluations).

_____**17.** Meeting with appropriate organizational officials to ensure common understanding for assessment objectives and the proposed rigor and scope of the assessment.

_____**18.** Developing a security assessment plan.

all security policies and associated procedures for implementing policy-compliant controls.

- The security policies for the information system and any associated implementing procedures.
- Individuals or groups responsible for the development, implementation, operation, and maintenance of security controls.
- Any materials (security plans, records, schedules, assessment reports, after-action reports, agreements, authorization packages) associated with the implementation and operation of security controls.
- The objects to be assessed.

The availability of essential documentation; as well as, access to key organizational personnel and the information system being assessed, are paramount to a successful assessment of the security controls.

When building secure organizations, one must consider both the technical expertise and the level of independence required in selecting security control assessors. Organizations must ensure that security control assessors possess the required skills and technical expertise to successfully carry out assessments of system-specific, hybrid, and common controls. This includes knowledge of and experience with the specific hardware, software, and firmware components employed by the organization. An independent assessor is any individual or group capable of conducting an impartial assessment of security controls employed within or inherited by an information system.

Impartiality implies that assessors are free from any perceived or actual conflicts of interest with respect to the development, operation, and/or management of the information system or the determination of security control effectiveness. The authorizing official or designated representative determines the required level of independence for security control assessors based on the results of the security categorization process for the information system and the ultimate risk to organizational operations and assets, individuals, other organizations. The authorizing official determines if the level of assessor independence is sufficient to provide confidence that the assessment results produced are sound and can be used to make a risk-based decision on whether to place the information system into operation or continue its operation.

Independent security control assessment services can be obtained from other elements within the organization or can be contracted to a public- or private-sector entity outside of the organization. In special situations—for example, when the organization that owns the information system is small or the organizational structure requires that the security control assessment be accomplished by individuals that are in the developmental, operational, and/or management chain of the system owner—independence in the assessment process can be achieved by ensuring that the assessment results are carefully reviewed and analyzed by an independent team of experts to validate the completeness, consistency, and veracity of the results.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Security, by its very nature, is inconvenient, and the more robust the security mechanisms, the more inconvenient the process becomes.
2. True or False? As though employees' desire to share data is enough of a threat to proprietary information, many business professionals want access to data from anywhere they work, on a variety of devices.
3. True or False? Many businesses believe that if they purchase enough equipment, they can create a secure infrastructure.
4. True or False? For most organizations, the cost of creating a weak security posture is seen as a necessary evil, similar to purchasing insurance.
5. True or False? In addressing the security needs of an organization, it is common for professionals to succumb to some very common misconceptions.

Multiple Choice

1. Many businesses believe that if they purchase enough equipment, they can create a secure:
   A. Firewall
   B. Workstation
   C. Ecommerce
   D. Organization
   E. Infrastructure
2. Once threats and risks are identified, you can take one of four steps, except which of the following?
   A. Ignore the risk.
   B. Accept the risk.
   C. Transfer the risk.
   D. Identify the risk.
   E. Mitigate the risk.
3. Just as implementing a robust, secure environment is a dynamic process; creating a highly skilled staff of security professionals is a:
   A. dynamic process.
   B. technical infrastructure.
   C. vendor-neutral program.
   D. work environment.
   E. professional affiliation.

4. What is the largest security-related organization in the world that focuses primarily on physical security, but has more recently started addressing computer security as well?
   A. ISACA
   B. HTCIA
   C. ISSA
   D. ASIS
   E. InfraGard
5. Arguably one of the best ways to determine whether an employee has a strong grasp of information security concepts is if she or he can achieve the Certified Information Systems Security Professional (CISSP) certification. Candidates for this certification are tested on their understanding of the following knowledge domains, except which one:
   A. Proprietary information
   B. Access Control
   C. Cryptography
   D. Operations security
   E. Security architecture

EXERCISE

Problem

With regards to building a secure organization, the security assessment team (SAT) should determine organizational policies and procedures, the privileged commands for which dual authorization is to be enforced; and the information system which enforces dual authorization based on organizational policies and procedures for organization-defined privileged commands. What should the SAT examine with regards to access enforcement potential assessment methods and objects?

Hands-On Projects

Project

With regards to building a secure organization, the security assessment team (SAT) should determine how the organization: defines applicable policy for controlling the flow of information within the system and between interconnected systems; defines approved authorizations for controlling the flow of information within the system and between interconnected systems in accordance with applicable policy; and the information system enforces approved authorizations for controlling the flow of information within the system and between interconnected systems in accordance with applicable policy. What should the SAT examine with regards to information flow enforcement potential assessment methods and objects?

Case Projects

Problem

With regards to building a secure organization, what should the security assessment team (SAT) examine with regards to security assessment and authorization?

Optional Team Case Project

Problem

With regards to building a secure organization, the security assessment team (SAT) should determine how the organization: develops a contingency plan for the information system that: identifies essential missions and business functions and associated contingency.

Requirements: provides recovery objectives, restoration priorities, and metrics; addresses contingency roles, responsibilities, assigned individuals with contact information; addresses maintaining essential missions and business functions despite an information system disruption, compromise, or failure; addresses eventual, full information system restoration without deterioration of the security measures originally planned and implemented; and is reviewed and approved by designated officials within the organization. The SAT should also determine how the organization: defines key contingency personnel (identified by name and/or by role) and organizational elements designated to receive copies of the contingency plan; and distributes copies of the contingency plan to organization-defined key contingency personnel and organizational elements. What should the SAT examine with regards to contingency planning?

Chapter 2

A Cryptography Primer

Scott R. Ellis, EnCE, RCA
kCura – Relativity Infrastructure Engineering, Manager

Cryptography, as a word, literally means the "study of hidden writing." It comes from the Greek κρυπτός, "hidden, secret"; and from γράφειν, graphein, "writing," or -λογία, -logia, "study."[1] In practice, it is so much more than that. The 0s and 1s of compiled software binary, something that frequently requires encryption, can hardly be considered "writing." Were a new word for cryptography to be invented today, it would probably be "secret communications." It follows then that, rather than point to the first altered writing as the origins of cryptography, we must look to the origins of communication and to the first known alterations of it in any form. Historically, then, you might say that cryptography is a built-in defense mechanism, as a property of language. As you'll see in this chapter, ultimately this dependency is also the final, greatest weakness of any cryptographic system, even the perceivably unbreakable AES system. From unique, cultural body language to language itself, to our every means of communication, it is in our nature to want to prevent others who would do us harm from intercepting private communications (which could be about them!). Perhaps nothing so perfectly illustrates this fact as the art of cryptography. It is, in its purpose, an art form entirely devoted to the methods whereby we can prevent information from falling into the hands of those who would use it against us—our enemies.

Since the beginning of sentient language, cryptography has been a part of communication. It is as old as language itself. In fact, one could make the argument that the desire and ability to encrypt communication, to alter a missive in such a way so that only the intended recipient may understand it, is an innate ability hard-wired into the human genome. Aside from the necessity to communicate, it could very well be what led to the development of language itself. Over time, languages and dialects evolved, as we can see with Spanish, French, Portuguese, and Italian—all of which derived from Latin. People who speak French have a great deal of trouble understanding people who speak Spanish, and vice versa. The profusion of Latin cognates in these languages is undisputed, but generally speaking, the two languages are so far removed that they are not dialects but rather separate languages. But why is this? Certain abilities, such as walking, are built into our nervous systems; other abilities, such as language, are not. From pig Latin to whispering circles to word jumbles, to languages so foreign that only the native speakers understand them, to diverse languages and finally modern cryptography, it is in our nature to keep our communications secret.

So why isn't language hard-wired into our nervous system, as it is with bees, who are born knowing how to tell another bee how far away a flower is, as well as the quantity of pollen and whether there is danger present? Why don't we humans all speak the exact same language? The reason is undoubtedly because humans, unlike bees, understand that knowledge is power, and knowledge is communicated via spoken and written words. Plus we weren't born with giant stingers with which to sting people we don't like. With the development of evolving languages innate in our genetic wiring, the inception of cryptography was inevitable.

In essence, computer-based cryptography is the art of creating a form of communication that embraces the following precepts:

- It can be readily understood by the intended recipients.
- It cannot be understood by unintended recipients
- It can be adapted and changed easily with relatively small modifications, such as a changed passphrase or word.

Any artificially created lexicon, such as the Pig Latin of children, pictograph codes, gang-speak, or corporate lingo—and even the names of music albums, such as *Four Flicks*—are all manners of cryptography where real text, sometimes not so ciphered, is hidden in what

1. Henry Liddell and Robert Scott, *Greek-English Lexicon*, Oxford University Press (1984).

appears to be plain text. They are attempts at hidden communications.

1. WHAT IS CRYPTOGRAPHY? WHAT IS ENCRYPTION?

Ask any ancient Egyptian and he'll undoubtedly define *cryptography* as the practice of burying the dead so that they cannot be found again. The Egyptians were very good at it; thousands of years later, new crypts are still being discovered. The Greek root *krypt* literally means "a hidden place," and as such it is an appropriate base for any term involving cryptology. According to the Online Etymology Dictionary, *crypto-* as a prefix, meaning "concealed, secret," has been used since 1760, and from the Greek *graphikos*, "of or for writing, belonging to drawing, picturesque." Together, *crypto* + *graphy* would then mean "hiding place for ideas, sounds, pictures, or words." *Graph*, technically from its Greek root, is "the art of writing." *Encryption*, in contrast, merely means the act of carrying out some aspect of cryptography. *Cryptology*, with its *-ology* ending, is the study of cryptography. Encryption is subsumed by cryptography.

How Is Cryptography Done?

For most information technology occupations, knowledge of cryptography is a very small part of a broader skill set and is generally limited to relevant applications. The argument could be made that this is why the Internet is so extraordinarily plagued with security breaches. The majority of IT administrators, software programmers, and hardware developers are barely cognizant of the power of true cryptography. Overburdened with battling the plague that they inherited, they can't afford to devote the time or resources needed to implement a truly secure strategy. And the reason, as we shall see, is that, as good as cryptographers can be, for every cryptographer there is a decryptographer working just as diligently to decipher a new encryption algorithm.

Traditionally, cryptography has consisted of any means possible whereby communications may be encrypted and transmitted. This could be as simple as using a language with which the opposition is not familiar. Who hasn't been in a place where everyone around them was speaking a language they didn't understand? There are thousands of languages in the world; nobody can know them all. As was shown in World War II, when the Allied forces used Navajo as a means of communicating freely, some languages are so obscure that an entire nation may not contain one person who speaks it! All true cryptography is composed of three parts: a cipher, an original message, and the resultant encryption. The *cipher* is the method of encryption used. Original messages are referred to as *plain text* or as *clear text*. A message that is transmitted without encryption is said to be sent "in the clear." The resultant message is called *ciphertext* or *cryptogram*. This part of the chapter begins with a simple review of cryptography procedures and carries them through; each section builds on the next to illustrate the principles of cryptography.

2. FAMOUS CRYPTOGRAPHIC DEVICES

The past few hundred years of technical development and advances have brought greater and greater means to decrypt, encode, and transmit information. With the advent of the most modern warfare techniques and the increase in communication and ease of reception, the need for encryption has never been greater.

World War II publicized and popularized cryptography in modern culture. The Allied forces' ability to capture, decrypt, and intercept Axis communications is said to have hastened the end of the war by several years. Next we take a quick look at some famous cryptographic devices from that era.

The Lorenz Cipher

The Lorenz cipher machine was an industrial-strength ciphering machine used in teleprinter circuits by the Germans during World War II. Not to be confused with its smaller cousin, the Enigma machine, the Lorenz cipher could possibly be best compared to a virtual private network tunnel for a telegraph line—only it wasn't sending Morse code, it was using a code not unlike a sort of American Standard Code for Information Interchange (ASCII) format. A grand-daddy of sorts, called the Baudot code, was used to send alphanumeric communications across telegraph lines. Each character was represented by a series of 5 bits.

The Lorenz cipher is often confused with the famous Enigma, but unlike the Enigma (which was a portable field unit), the Lorenz cipher could receive typed messages, encrypt them, and send them to another distant Lorenz cipher, which would then decrypt the signal. It used a pseudorandom cipher XOR'd (an encryption algorithm) with plaintext. The machine would be inserted inline as an attachment to a Lorenz teleprinter. Figure 2.1 is a rendered drawing from a photograph of a Lorenz cipher machine.

Enigma

The Enigma machine was a field unit used in World War II by German field agents to encrypt and decrypt

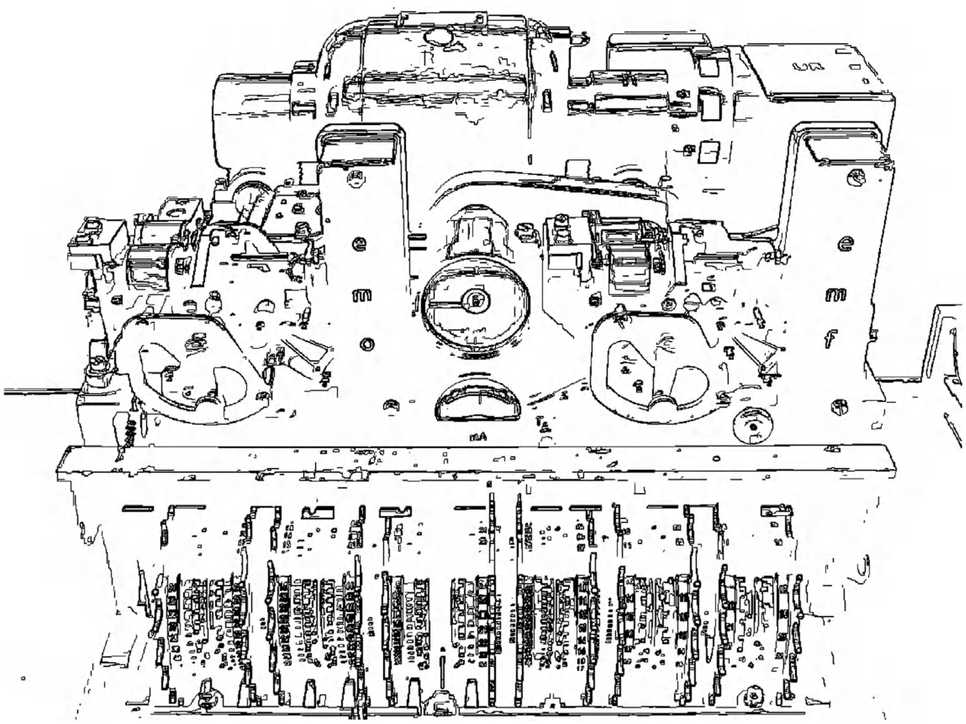

FIGURE 2.1 The Lorenz machine was set inline with a teletype to produce encrypted telegraphic signals.

messages and communications. Similar to the Feistel function of the 1970s, the Enigma machine was one of the first mechanized methods of encrypting text using an iterative cipher. It employed a series of rotors that, with some electricity, a light bulb, and a reflector, allowed the operator to either encrypt or decrypt a message. The original position of the rotors, set with each encryption and based on a prearranged pattern that in turn was based on the calendar, allowed the machine to be used, even if it was compromised.

When the Enigma was in use, with each subsequent key press, the rotors would change in alignment from their set positions in such a way that a different letter was produced each time. The operator, with a message in hand, would enter each character into the machine by pressing a typewriter-like key. The rotors would align, and a letter would then illuminate, telling the operator what the letter *really* was. Likewise, when enciphering, the operator would press the key and the illuminated letter would be the cipher text. The continually changing internal flow of electricity that caused the rotors to change was not random, but it did create a polyalphabetic cipher that could be different each time it was used.

3. CIPHERS

Cryptography is built on one overarching premise: the need for a cipher that can reliably, and portably, be used to encrypt text so that, through any means of cryptanalysis—differential, deductive, algebraic, or the like—the ciphertext cannot be undone with any available technology. Throughout the centuries, there have been many attempts to create simple ciphers that can achieve this goal. With the exception of the One Time Pad, which is not particularly portable, success has been limited. Let's look at a few of these methods now.

The Substitution Cipher

In this method, each letter of the message is replaced with a single character. See Table 2.1 for an example of a substitution cipher. Because some letters appear more often and certain words are used more than others, some ciphers are extremely easy to decrypt and can be deciphered at a glance by more practiced cryptologists.

By simply understanding probability and with some applied statistics, certain metadata about a language can be derived and used to decrypt any simple, one-for-one substitution cipher. Decryption methods often rely on understanding the context of the *ciphertext*. What was encrypted—business communication? Spreadsheets? Technical data? Coordinates? For example, using a hex editor and an access database to conduct some statistics, we can use the information in Table 2.2 to gain highly specialized knowledge about the data in Chapter 33, "Computer Forensics," by Scott R. Ellis, in this book. A long chapter at nearly 25,000 words, it provides a

TABLE 2.1 A Simple Substitution Cipher. Letters are Numbered by their Order in the Alphabet, to Provide a Numeric Reference Key. To Encrypt a Message, the Letters are Replaced, or Substituted, by the Numbers. This is a Particularly Easy Cipher to Reverse.

TABLE 2.2 Statistical Data of Interest in Encryption. An Analysis of a Selection of a Manuscript (in this case, the preedited version of Chapter 33 of this book) can Provide Insight into the Reasons that Good Ciphers Need to be Developed.

Character Analysis	Count
Number of distinct alphanumeric combinations	1958
Distinct characters	68
Number of four-letter words	984
Number of five-letter words	1375

sufficiently large statistical pool to draw some meaningful analyses.

Table 2.3 gives additional data about the occurrence of specific words in Chapter 33. Note that because it is a technical text, words such as *computer, files, email*, and *drive* emerge as leaders. Analysis of these leaders can reveal individual and paired alpha frequencies. Being armed with knowledge about the type of communication can be very beneficial in decrypting it.

Further information about types of data being encrypted includes word counts by length of the word. Table 2.4 contains such a list for Chapter 33. This information can be used to begin to piece together useful and meaningful short sentences, which can provide cues to longer and more complex structures. It is exactly this sort of activity that good cryptography attempts to defeat.

Were it encrypted using a simple substitution cipher, a good start to deciphering Chapter 33 could be made using the information we've gathered. As a learning exercise, game, or logic puzzle, substitution ciphers are quite useful. Some substitution ciphers that are more elaborate can be just as difficult to crack. Ultimately, though, the weakness behind a substitution cipher is the fact that the

TABLE 2.3 Five-letter Word Recurrences in Chapter 33: A Glimpse of the Leading Five-letter Words found in the Preedited Manuscript. Once Unique Letter Groupings have been Identified, Substitution, Often by Trial and Error, can Result in a Meaningful Reconstruction that Allows the Entire Cipher to be Revealed.

ciphertext remains a one-to-one, directly corresponding substitution; ultimately, anyone with a pen and paper and a large enough sample of the ciphertext can defeat it. Through use of a computer, deciphering a simple substitution cipher becomes child's play.

Example 2.1 A Sample Cryptogram. Try this Out: Gv Vw, Dtwvg?

Hint: Caesar said it, and it is in Latin.[2]

The Shift Cipher

Also known as the Caesar cipher, the shift cipher is one that anyone can readily understand and remember for decoding. It is a form of the substitution cipher. By shifting the alphabet a few positions in either direction, a simple sentence can become unreadable to casual inspection. Example 2.1 is an example of such a shift.

Interestingly, for cryptogram word games, the spaces are always included. Often puzzles use numbers instead of letters for the substitution. Removing the spaces in this particular example can make the ciphertext somewhat more secure. The possibility for multiple solutions becomes an issue; any number of words might fit the pattern.

Today many software tools are available to quickly and easily decode most cryptograms (at least, those that are not written in a dead language). You can have some fun with these tools; for example, the name Scott Ellis, when decrypted, turns into Still Books. The name of a friend of the author's decrypts to "His Sinless." It is apparent, then, that smaller-sample simple substitution ciphers can have more than one solution.

Much has been written and stated about frequency analysis; it is considered the "end-all and be-all" with respect to cipher decryption. Frequency analysis is not to be confused with cipher breaking, which is a modern attack against the actual cryptographic algorithms themselves. However, to think of simply plugging in some numbers generated from a Google search is a bit naïve. The frequency chart in Table 2.5 is commonplace on the Web.

It is beyond the scope of this chapter to delve into the accuracy of the table, but suffice it to say that our own analysis of Chapter 33's 118,000 characters, a technical text, yielded a much different result; see Table 2.6. Perhaps it is the significantly larger sample and the fact that it is a technical text that makes the results different after the top two. Additionally, where computers are concerned, an actual frequency analysis would take into consideration all ASCII characters, as shown in Table 2.6.

Frequency analysis is not difficult; once all the letters of a text are pulled into a database program, it is fairly straightforward to do a count of all the duplicate values. The snippet of code in Example 2.2 demonstrates one

way in which text can be transformed into a single column and imported into a database.

The cryptograms that use formatting (every word becomes the same length) are considerably more difficult for basic online decryption programs to crack. They must take into consideration spacing and word lengths when considering whether or not a string matches a word. It stands to reason, then, that the formulation of the cipher—where a substitution that is based partially on frequency similarities and with a whole lot of

obfuscation so that when messages are decrypted they have ambiguous or multiple meanings—would be desirable for simple ciphers. However, this would only be true for very short and very obscure messages that could be code words to decrypt other messages or could simply be sent to misdirect the opponent. The amount of ciphertext needed to successfully break a cipher is called *unicity distance*. Ciphers with small unicity distances are weaker than those with large ones.

Example 2.2

```
Sub Letters2column ()
Dim bytText () As Byte
Dim bytNew() As Byte
Dim lngCount As Long
With ActiveDocument.Content
bytText = .Text
ReDim bytNew((((UBound(bytText()) + 1) * 2) − 5))
For lngCount = 0 To (UBound(bytText()) − 2) Step 2
bytNew((lngCount * 2)) = bytText(lngCount)
bytNew(((lngCount * 2) + 2)) = 13
Next lngCount
.Text = bytNew()
End With
End Sub
```

Ultimately, substitution ciphers are vulnerable to either word-pattern analysis, letter-frequency analysis, or some combination of both. Where numerical information is encrypted, tools such as Benford's Law can be used to elicit patterns of numbers that *should* be occurring. Forensic techniques incorporate such tools to uncover accounting fraud. So, though this particular cipher is a child's game, it is useful in that it is an underlying principle of cryptography and should be well understood before continuing. The primary purpose of discussing it here is as an introduction to ciphers.

Further topics of interest and places to find information involving substitution ciphers are the chi-square statistic, Edgar Allan Poe, Sherlock Holmes, Benford's Law, Google, and Wikipedia. For example, an Internet search for Edgar Allan Poe + cryptography will lead you to articles that detail how Poe's interest in the subject, and his use of it in stories such as "The Gold-Bug," served to popularize and raise awareness of cryptography in the general public.

The Polyalphabetic Cipher

The preceding clearly demonstrated that though the substitution cipher is fun and easy, it is also vulnerable and weak. It is especially susceptible to frequency analysis. Given a large enough sample, a cipher can easily be broken by mapping the frequency of the letters in the ciphertext to the frequency of letters in the language or dialect of the ciphertext (if it is known). To make ciphers more difficult to crack, Blaise de Vigenère from the sixteenth-century court of Henry III of France proposed a polyalphabetic substitution. In this cipher, instead of a one-to-one relationship, there is a one-to-many. A single letter can have multiple substitutes. The Vigenère solution was the first known cipher to use a keyword.

It works like this: First, a *tableau* is developed, as in Table 2.7. This tableau is a series of shift ciphers. In fact, since there can be only 26 additive shift ciphers, it is all of them.

In Table 2.7, a table in combination with a keyword is used to create the cipher. For example, if we choose the keyword *rockerrooks*, overlay it over the plaintext, and cross-index it to Table 2.7, we can produce the ciphertext. In this example, the top row is used to look up the plaintext, and the leftmost column is used to reference the keyword.

For example, we lay the word *rockerrooks* over the sentence, "Ask not what your country can do for you." Line 1 is the keyword, line 2 is the plain text, and line 3 is the ciphertext.

Keyword: ROC KER ROOK SROC KERROOK SRO CK ERR OOK
Plaintext: ASK NOT WHAT YOUR COUNTRY CAN DO FOR YOU
Ciphertext: RGM XSK NVOD QFIT MSLEHFI URB FY JFI MCE

The similarity of this tableau to a mathematical table like the one shown in Table 2.8 becomes apparent. Just think letters instead of numbers, and it becomes clear how this works. The top row is used to "look up" a letter from the plaintext, the leftmost column is used to locate the overlaying keyword letter, and where the column and the row intersect is the ciphertext.

TABLE 2.7 Vigenère's Tableau Arranges all of the Shift Ciphers in a Single Table. It then Implements a Keyword to Create a more Complex Cipher than the Simple Substitution or Shift Ciphers. The Number *of spurious keys,* that is, Bogus Decryptions that result from Attempting to Decrypt a Polyalphabetic Encryption, is Greater than those Created during the Decryption of a Single Shift Cipher.

This similarity is, in fact, the weakness of the cipher. Through some creative "factoring," the length of the keyword can be determined. Since the tableau is, in practice, a series of shift ciphers, the length of the keyword determines how many ciphers are used. The keyword *rockerrook*, with only six distinct letters, uses only six ciphers. Regardless, for nearly 300 years many people believed the cipher to be unbreakable.

The Kasiski/Kerckhoff Method

Now let's look at Kerckhoff's principle—"only secrecy of the key provides security." (This principle is not to be confused with Kirchhoff's law, a totally different man and rule.) In the nineteenth century, Auguste Kerckhoff stated that essentially, a system should still be secure, even when everyone knows everything about the system (except the password). Basically, his feeling was that if

TABLE 2.8 The Multiplication Table is the Inspiration for the Vigenère Tableau.

10	10	20	30	40	50	60	70	80	90	100

more than one person knows something, it's no longer a secret. Throughout modern cryptography, the inner workings of cryptographic techniques have been well known and published. Creating a portable, secure, unbreakable code is easy if nobody knows how it works. The problem lies in the fact that we people just can't keep a secret!

Example 2.3 A Repetitious, Weak Keyword Combines with Plaintext to Produce an Easily Deciphered Ciphertext

I	to	to	toto	to	to	toto	to
Plaintext	It	is	what	it	is,	isn't	it?
Ciphertext	BH	BG	PVTH	BH	BG	BGGH	BH

In 1863 Friedrich Kasiski, a Prussian major, proposed a method to crack the Vigenère cipher.[3] Briefly, his method required that the cryptographer deduce the length of the keyword used and then dissect the cryptogram into a corresponding number of ciphers. This is accomplished by simply examining the distance between repeated strings in the ciphertext. Each cipher would then be solved independently. The method required that a suitable number of bigrams be located. A *bigram* is a portion of the ciphertext, two characters long, that repeats itself in a discernible pattern. In Example 2.3, a repetition has been deliberately made simple with a short keyword (*toto*) and engineered by crafting a harmonic between the keyword and the plaintext.

This might seem an oversimplification, but it effectively demonstrates the weakness of the polyalphabetic cipher. Similarly, the polyalphanumeric ciphers, such as the Gronsfeld cipher, are even weaker since they use 26 letters and 10 digits. This one also happens to decrypt to "On of when on of," but a larger sample with such a weak keyword would easily be cracked by even the least intelligent Web-based cryptogram solvers. The harmonic is created by the overlaying keyword with the underlying text; when the bigrams "line up" and repeat themselves, the highest frequency will be the length of the password. The distance between the two occurrences will be the length of the password. In Example 2.3, we see BH and BG repeating, and then we see BG repeating at a very tight interval of 2, which tells us the password might be two characters long and based on two shift ciphers that, when decrypted side by side, will make a real word. Not all bigrams will be indicators of this, so some care must be taken. As can be seen, BH repeats with an interval of 8, but the password is not eight digits long (but it is a factor of 8!). By locating the distance of all the repeating bigrams and factoring them, we can deduce the length of the keyword.

4. MODERN CRYPTOGRAPHY

Some of cryptography's greatest stars emerged in World War II. For the first time during modern warfare, vast resources were devoted to enciphering and deciphering communications. Both sides made groundbreaking advances in cryptography. Understanding the need for massive calculations (for the time—more is probably happening in the RAM of this author's PC over a period of five minutes than happened in all of the war), both sides developed new machinery—predecessors to the modern solid-state computers—that could be coordinated to perform the calculations and procedures needed to crack enemy ciphers.

The Vernam Cipher (Stream Cipher)

Gilbert Sandford Vernam (1890−1960) invented the stream cipher in 1917; a patent was issued on July 22, 1919. Vernam worked for Bell Labs, and his patent described a cipher in which a prepared key, on a paper tape, combined with plaintext to produce a transmitted ciphertext message. He did not use the term *d'art "XOR"* but did implement the exact same logic at the relay layer. The credit for automating cryptography goes to Vernam. He introduced the Baudot system, which is the Morse code of the teletype, to cryptography. In it, each character is represented by five units, or pulses. With the expectation that a set number of "pulses" would be transmitted over a given period of time, the pulse, or absence thereof, creates a system of zeroes and ones

3. David Kahn, *The Codebreakers —The Story of Secret Writing* (ISBN 0684831309), 1996, Scribner, New York, NY.

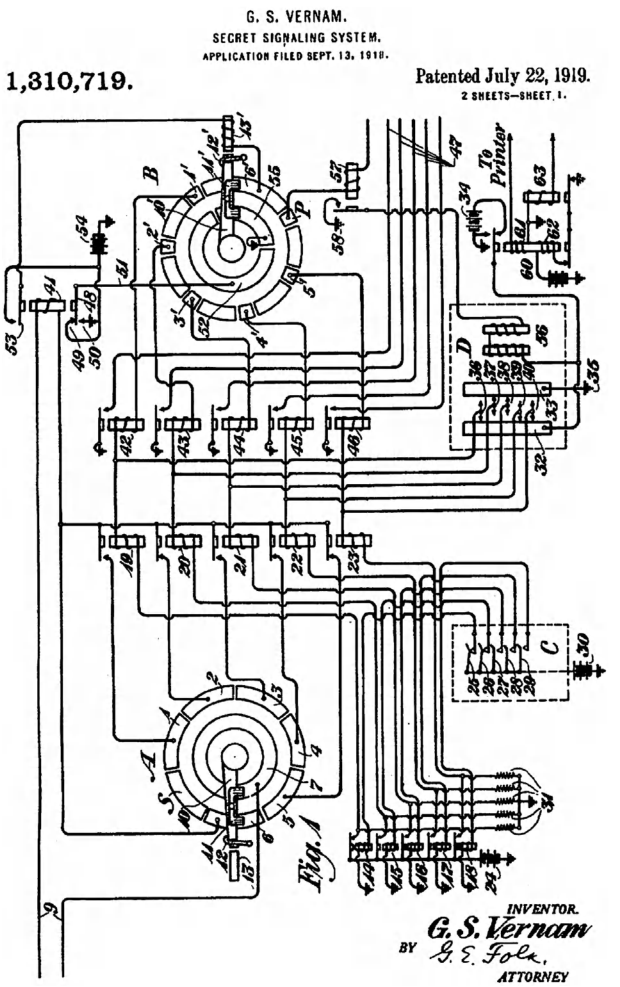

FIGURE 2.2 G. S. Vernam's Secret Signaling System introduced bit-by-bit enciphering using XOR technology to the world of cryptography for the first time.

that flesh out a binary system. Vernam was the first to suggest that a prepunched tape (cipher) could *combine* with the plaintext and yield difficult to crack ciphertext. The same tape would then be used to decrypt the ciphertext. Through testing and development, it became apparent that two tapes could be used and offset against one another to produce many different ciphers. Later, methods were derived for using a single stream of random numbers to create an unbreakable cipher. Physical problems barred this from gaining wide implementation; the logisitics of managing or transmitting the random cipher, and then knowing which message to which it applied, were simply insurmountable in wartime, where messaging increases dramatically. Regardless, Vernam's accomplishment of employing a method of automation to encryption cannot be underestimated. He developed a way whereby, using a series of magnets and relays, the cipher and plaintext pulses could be combined electrically.[4] Figure 2.2 is a page from the actual patent papers, Patent No. 1,310,719.[5]

In effect, the Vernam stream cipher and "one-time pad" ciphers are very similar; in fact, Vernam later co-invented it. The primary difference is that the "one-time pad" cipher dictates that a truly random stream cipher be used for the encryption. The stream cipher had no such requirement and used a different method of relay logic to combine a pseudorandom stream of bits with the plaintext bits. (The XOR process is discussed in more detail in the section on XOR ciphering.) In practice today, the Vernam cipher is any stream cipher in which pseudorandom or random text is combined with plaintext to produce cipher text that is the same length as the cipher. RC4 is a modern example of a Vernam cipher.

The One-Time Pad

The "one-time pad" cipher, attributed to Joseph Mauborgne, is perhaps one of the most secure forms of cryptography. It is very difficult to break if used properly, and if the key stream is perfectly random, the ciphertext gives away absolutely no details about the plaintext, which renders it unbreakable. And, just as the name suggests, it uses a single random key that is the same length as the entire message, and it uses the key only once. The word *pad* is derived from the fact that the key would be distributed in pads of paper, with each sheet torn off and destroyed as it was used.

There are several weaknesses to this cipher. We begin to see that the more secure the encryption, the more it will rely on other means of key transmission. The more a key has to be moved around, the more likely it is that someone who shouldn't have it will have it. The following weaknesses are apparent in this "bulletproof" style of cryptography:

- Key length has to equal plaintext length.
- It is susceptible to key interception; the key must be transmitted to the recipient, and the key is as long as the message!
- It's cumbersome, since it doubles the traffic on the line.
- The cipher must be perfectly random.
- One-time use is absolutely essential. As soon as two separate messages are available, the messages can be decrypted. Example 2.4 demonstrates this.

Since most people don't use binary, the author takes the liberty in Example 2.4 of using decimal numbers modulus 26 to represent the XOR that would take place in a bitstream encryption (see the section on the XOR cipher) that uses the method of the one-time pad.

4. David Kahn, *The Codebreakers—The Story of Secret Writing* (394–403), (Scribner, 1996).
5. U.S. Patent 1,310,719.

Example 2.4 Using the Random Cipher, a Modulus Shift Instead of an XOR, and Plaintext to Produce Ciphertext

A numeric value is assigned to each letter, as seen in Table 2.9. By assigning a numeric value to each letter, adding the plaintext value to the ciphertext value, modulus 26, yields a pseudo-XOR, or a wraparound Caesar shift that has a different shift for each letter in the entire message.

As this example demonstrates, by using the same cipher twice, a dimension is introduced that allows for the introduction of frequency analysis. By placing the two streams side by side, we can identify letters that are the same. In a large enough sample, where the ciphertext is sufficiently randomized, frequency analysis of the aligned values will begin to crack the cipher wide open because we know that they are streaming in a logical order—the order in which they were written. One of the chief advantages of twenty-first-century cryptography is that the "eggs" are scrambled and descrambled during decryption based on the key, which you don't, in fact, want people to know. If the same cipher is used repeatedly, multiple inferences can be made, and eventually the entire key can be deconstructed. Because plaintext 1 and plaintext 2 are so similar, this sample yields the following harmonics (in bold and boxed) as shown in Example 2.5.

TABLE 2.9 A Simple Key is Created so that Random Characters and Regular Characters May be Combined with a Modulus Function. Without the Original Cipher, this Key is Meaningless Intelligence. It is used here in a Similar Capacity as an XOR, which is also a Function that Everyone Knows how to do.

Key																									
a	b	e	d	e	f	g	h	i	j	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26

Example 2.5

The two ciphertexts, side by side, show a high level of harmonics. This indicates that two different ciphertexts actually have the same cipher. Where letters are different, since XOR is a known process and our encryption technique is also publicly known, it's a simple matter to say that $r = 18$, $e = 5$ (see Table 2.9) and thus construct an algorithm that can tease apart the cipher and ciphertext to produce plaintext.

```
k m a m v d u a r f l s k h a i e a b p h w m w g n j l w u c k m t j s (ciphertext 1)
k m a m v d u a e p m f k l i f j f o z u a c y b i c e q h m k m t j s (ciphertext 2)
```

Some Statistical Tests for Cryptographic Applications By Adrian Fleissig

In many applications, it is often important to determine if a sequence is random. For example, a random sequence provides little or no information in cryptographic analysis. When estimating economic and financial models, it is important for the residuals from the estimated model to be random. Various statistical tests can be used to evaluate whether or not a sequence is actually a random sequence. For a truly random sequence, it is assumed that each element is generated independently of any prior and/or future elements. A statistical test is used to compute the probability that the observed sequence is random compared to a truly random sequence. The procedures have test statistics that are used to evaluate the null hypothesis, which typically assumes that the observed sequence is random. The alternative hypothesis is that the sequence is nonrandom. Thus failing to accept the null hypothesis, at some critical level selected by the researcher, suggests that the sequence may be nonrandom.

There are many statistical tests to evaluate for randomness in a sequence, including Frequency Tests, Runs Tests, Discrete Fourier Transforms, and Serial Tests. The tests statistics often have chi-square or standard normal distributions that are used to evaluate the hypothesis. While no test is overall superior to the other tests, a Frequency or Runs Test is a good starting point to examine for nonrandomness in a sequence. As an example, a Frequency or Runs Test typically evaluates if the number of zeros and ones in a sequence are about the same, as would be the case if the sequence was truly random.

It is important to examine the results carefully. For example, the researcher may incorrectly fail to accept the null hypothesis that the sequence is random and thereby makes a Type I Error. Incorrectly accepting the null of randomness when the sequence is actually nonrandom results in committing a Type II Error. The reliability of the results depends on having a sufficiently large number of elements in a sequence. In addition, it is important to perform alternative tests to evaluate if a sequence is random.[6]

Cracking Ciphers

One method of teasing out the frequency patterns is through the application of some sort of mathematical formula to test a hypothesis against reality. The chi-square test is perhaps one of the most commonly used; it allows someone to use what is called *inferential statistics* to draw certain inferences about the data by testing it against known statistical distributions.

Using the chi-square test against an encrypted text would allow certain inferences to be made, but only where the contents, or the type of contents (random or of an expected distribution), of the text were known. For example, someone may use a program that encrypts files. By creating the null hypothesis that the text is completely random and by reversing the encryption steps, a block cipher may emerge as the null hypothesis is disproved through the chi-square test. This would be done by reversing the encryption method and XORing against the bytes with a block created from the known text. At the point where the nonencrypted text matches the positioning of the encrypted text, chi-square would reveal that the output is not random and the block cipher would be revealed.

$$\text{Chi-squared} = \ldots(\text{observed-expected})2/(\text{expected})$$

Observed would be the actual zero/one ratio produced by XORing the data streams together, and expected would be the randomness of zeroes and ones (50/50) in a body of pseudorandom text.

Independent of having a portion of the text, a large body of encrypted text could be reverse encrypted using a block size of all zeroes. In this manner it may be possible to tease out a block cipher by searching for nonrandom block-sized strings. Modern encryption techniques generate many, many block cipher permutations that are layered against previous iterations ($n - 1$) of permutated blocks. The feasibility of running such decryption techniques would require both a heavy-duty programmer and a statistician, an incredible amount of processing power, and in-depth knowledge of the encryption algorithm used. An unpublished algorithm would render such testing worthless.

The methods and procedures used in breaking encryption algorithms are used throughout society in many applications where a null hypothesis needs to be tested. Forensic consultants use pattern matching and similar decryption techniques to combat fraud on a daily basis. Adrian Fleissig, a seasoned economist, makes use of many statistical tests to examine corporate data (see the sidebar, "Some Statistical Tests for Cryptographic Applications").

The XOR Cipher and Logical Operands

In practice, the XOR cipher is not so much a cipher as it is a mechanism whereby ciphertext is produced. *Random binary stream cipher* would be a better term. The terms *XOR*, *logical disjunction*, and *inclusive* may be used interchangeably. Most people are familiar with the logical functions of speech, which are words such as *and, or, nor*, and *not*. A girl can tell her brother, "Mother is either upstairs or at the neighbor's," which means she could be in either state, but you have no way of knowing which

6. Adrian Fleissig is the Senior Economist of Counsel for RGL Forensics, 2006–present. He is also a full professor, California State University Fullerton (CSUF) with a joint Ph.D. in Economics and Statistics from North Carolina State University in 1993.

one it is. The mother could be in either place, and you can't infer from the statement the greater likelihood of either. The outcome is undecided.

Alternatively, if a salesman offers a customer either a blue car or a red car, the customer knows that he can have red or he can have blue. Both statements are true. Blue cars and red cars exist simultaneously in the world. A person can own both a blue car and a red car. But Mother will never be in more than one place at a time. Purportedly, there is widespread belief that no author has produced an example of an English *or* sentence that appears to be false because both of its inputs are true.[7] Quantum physics takes considerable exception to this statement (which explains quantum physicists) at the quantum-mechanical level. In the Schrodinger cat experiment, the sentence "The cat is alive or dead" or the statement "The photon is a particle and a wave until you look at it, then it is a particle or a wave, depending on how you observed it" both create a quandary for logical operations, and there are no Venn diagrams or words that are dependent on time or quantum properties of the physical universe. Regardless of this exception, when speaking of things in the world in a more rigorously descriptive fashion (in the macroscopically non-phenomenological sense), greater accuracy is needed.

To create a greater sense of accuracy in discussions of logic, the operands as listed in Figure 2.3 were created. When attempting to understand this chart, the best thing to do is to assign a word to the A and B values and think of each Venn diagram as a universe of documents, perhaps in

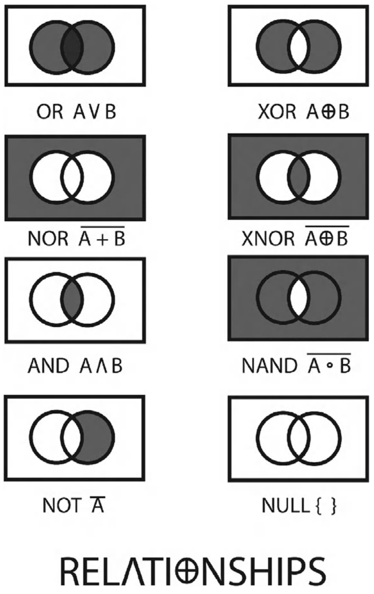

FIGURE 2.3 In each Venn diagram, the possible outcome of two inputs is decided.

7. Barrett and Stenner, "The Myth of the Exclusive'Or,'" *Mind*, 80 (317), 116−121, 1971. [First names or initials needed for authors]

Example 2.6 Line 1 and Line 2 are Combined with an XOR Operand to Produce Line 3

Line 1, plaintext :	1 0 0 1 1 1 0 1 0 1 1 0 1 1 1 1
Line 2, random cipher "":	1 0 0 0 1 1 0 1 0 1 0 0 1 0 0 1
Line 3, XOR ciphertext:	0 0 0 1 0 0 0 0 0 0 1 0 0 1 0 0

a document database or just on a computer being searched. If A stands for the word *tree* and B for *frog*, then each letter simply takes on a very significant and distinct meaning.

In computing, it is traditional that a value of 0 is false and a value of 1 is true. An XOR operation, then, is the determination of whether two possibilities can be combined to produce a value of true or false, based on whether both operations are true, both are false, or one of the values is true.

1 XOR 1 = 0
0 XOR 0 = 0
1 XOR 0 = 1
0 XOR 1 = 1

In an XOR operation, if the two inputs are different, the resultant is TRUE, or 1. If the two inputs are the same, the resultant value is FALSE, or 0.

In Example 2.6, the first string represents the plaintext and the second line represents the cipher. The third line represents the ciphertext. If, and only exactly if, just one of the items has a value of TRUE, the results of the XOR operation will be true.

Without the cipher, and if the cipher is truly random, decoding the string becomes impossible. However, as in the one-time pad, if the same cipher is used, then (1) the cryptography becomes vulnerable to a known text attack, and (2) it becomes vulnerable to statistical analysis. Example 2.7 demonstrates this by showing exactly where the statistical aberration can be culled in the stream. If we know they both used the same cipher, can anyone solve for Plaintext A and Plaintext B?

Block Ciphers

Block ciphers work similarly to the polyalphabetic cipher, with the exception that a block cipher pairs together two algorithms for the creation of ciphertext and its decryption. It is also somewhat similar in that, where the polyalphabetic cipher used a repeating key, the block cipher uses a permutating, yet repeating, cipher block. Each algorithm uses two inputs: a key and a "block" of bits, each of a set size. Each output block is the same size as the input block, the block being transformed by the key. The key, which is algorithm based, is able to select the permutation of its bijective mapping from 2^n, where n is equal to the number of bits in the *input* block. Often, when 128-bit encryption is discussed, it is referring to the size of the *input* block.

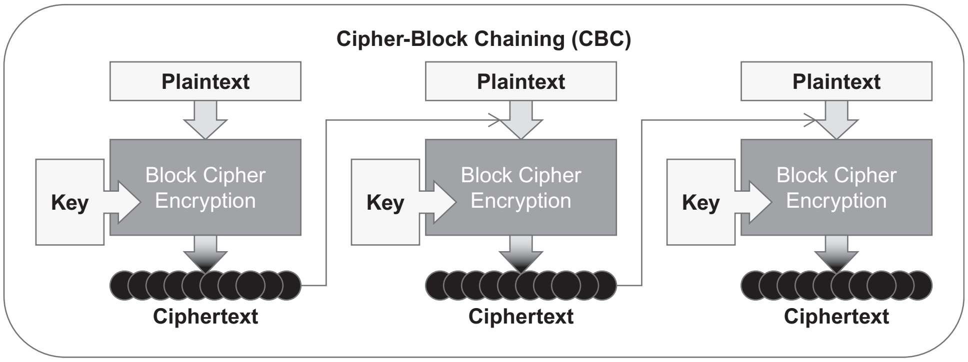

FIGURE 2.4 XOR chaining, or cipher-block chaining (CBC), is a method whereby the next block of plaintext to be encrypted is XOR'd with the previous block of ciphertext before being encrypted.

Typical encryption methods involve use of XOR chaining or some similar operation; see Figure 2.4.

Block ciphers have been very widely used since 1976 in many encryption standards. As such, cracking these ciphers became, for a long time, the top priority of cipher crackers everywhere. Block ciphers provide the backbone algorithmic technology behind most modern-era ciphers.

Example 2.7

To reconstruct the cipher if the plaintext is known, PlaintextA can be XOR'd to ciphertextB to produce cipherA! Clearly, in a situation where plaintext may be captured, using the same cipher key twice could completely expose the message. By using statistical analysis, the unique possibilities for PlaintextA and PlaintextB will emerge; *unique possibilities* means that for ciphertext = *x*, where the cipher is truly random, this should be at about 50 percent of the sample. Additions of ciphertext $n+1$ will increase the possibilities for unique combinations because, after all, these binary streams must be converted to text and the set of binary stream possibilities that will combine into ASCII characters is relatively small. Using basic programming skills, you can develop algorithms that will quickly and easily sort through this data to produce a deciphered result. An intelligent person with some time on her hands could sort it out on paper or in an Excel spreadsheet. When the choice is "The red house down the street from the green house is where we will meet" or a bunch of garbage, it begins to become apparent how to decode the cipher.

CipherA and PlaintextA are XOR'd to produce ciphertextA:

PlaintextA: 0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1
cipherA: 1 1 1 1 1 1 1 1 0 0 0 0 0 0 0 0
ciphertextA: 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1

PlaintextB and cipherA are XOR'd to produce ciphertextB:

ciphertextB: 0 0 0 0 0 0 0 0 1 1 1 1 1 1 1 1
cipherA: 1 1 1 1 1 1 1 1 0 0 0 0 0 0 0 0
PlaintextB: 1 1 1 1 1 1 1 1 0 0 0 0 0 0 0 0
| <—— Column 1 ——> || <——Column 2 —— |

Note: Compare ciphertextA to ciphertextB!

---

5. THE COMPUTER AGE

Many people consider January 1, 1970, as the dawn of the computer age. That's when Palo Alto Research Center (PARC) in California introduced modern computing; the graphical user interface (no more command line and punch cards), networking on an Ethernet, and object-oriented programming have all been attributed to PARC. The 1970s also featured the Unix clock, Alan Shepard on the moon, the U.S. Bicentennial, the civil rights movement, women's liberation, Robert Heinlein's sci-fi classic, *Stranger in a Strange Land*, the birth of my wife, and, most important to this chapter, modern cryptography. The late 1960s and early 1970s changed the face of the modern world at breakneck speed. Modern warfare reached tentative heights with radio-guided missiles, and warfare needed a new hero. And then there was the Data Encryption Standard, or DES; in a sense DES was the turning point for cryptography in that, for the first time, it fully leveraged the power of modern computing in its algorithms. The sky appeared to be the limit, but, unfortunately for those who wanted to keep their information secure, decryption techniques were not far behind.

Data Encryption Standard

In the mid-1970s, the U.S. government issued a public specification, through its National Bureau of Standards (NBS), called the Data Encryption Standard or, most commonly, DES. This could perhaps be considered the dawn of modern cryptography because it was very likely the first block cipher, or at least its first widespread implementation. But the 1970s were a relatively untrusting time. "Big Brother" loomed right around the corner (as per George Orwell's *1984*), and the majority of people didn't understand or necessarily trust DES. Issued under the NBS, now called the National Institute of Standards and Technology (NIST), hand in hand with the National Security Agency (NSA), DES led to tremendous interest in the reliability of the standard among academia's ivory towers. A shortened key length and the implementation of

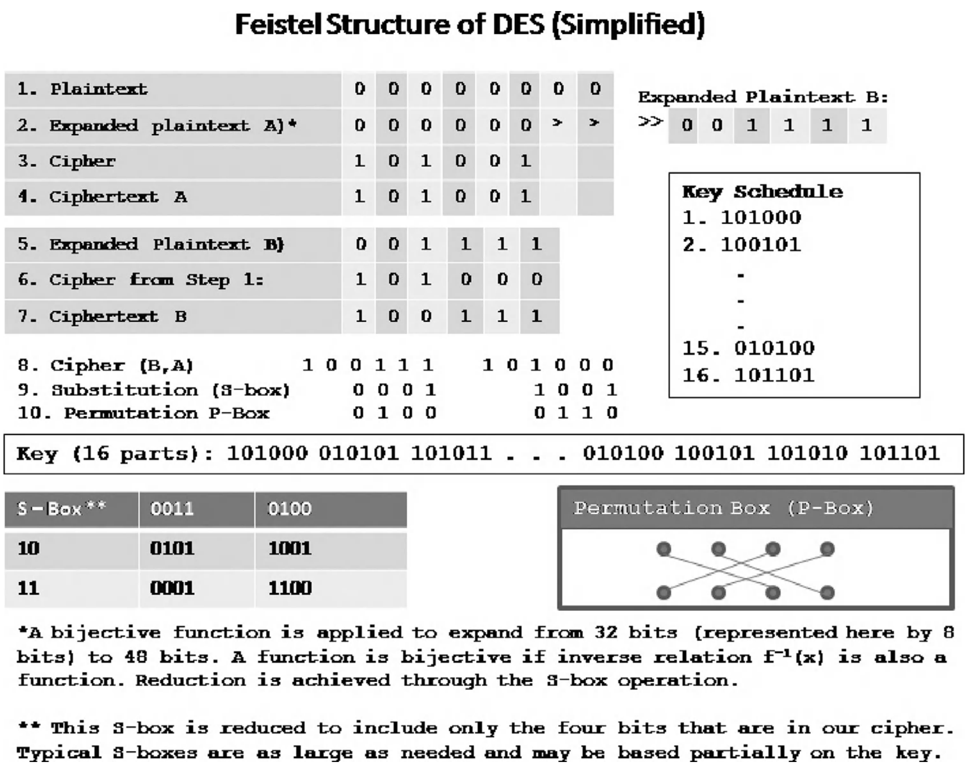

FIGURE 2.5 The Feistel function with a smaller key size.

substitution boxes, or "S-boxes," in the algorithm led many to think that the NSA had deliberately weakened the algorithms and left a security "back door" of sorts.

The use of S-boxes in the standard was not generally understood until the design was published in 1994 by Don Coppersmith. The S-boxes, it turned out, had been deliberately designed to prevent a sort of cryptanalysis attack called *differential cryptanalysis*, as was discovered by IBM researchers in the early 1970s; the NSA had asked IBM to keep quiet about it. In 1990 the method was "re"-discovered independently and, when used against DES, the usefulness of the S-boxes became readily apparent.

Theory of Operation

DES used a 64-bit block cipher combined with a mode of operation based on cipher-block chaining (CBC) called the *Feistel function*. This consisted of an initial expansion permutation followed by 16 rounds of XOR key mixing via subkeys and a key schedule, substitution (S-boxes), and permutation.[8] In this strategy, a block is increased from 32 bits to 48 bits (expansion permutation). Then the 48-bit block is divided in half. The first half is XORs, with parts of the key according to a key schedule. These are called subkeys. Figure 2.5 shows this concept in a simplified format.

The resulting cipher is then XOR'd with the half of the cipher that was not used in step 1. The two halves switch sides. Substitution boxes reduce the 48 bits down to 32 bits via a nonlinear function and then a permutation, according to a permutation table, takes place. Then the entire process is repeated again, 16 times, except in the last step the two halves are not flipped. Finally, this diffusive strategy produced via substitution, permutation, and key schedules creates an effective ciphertext. Because a fixed-length cipher, a block cipher, is used, the permutations and the S-box introduce enough confusion that the cipher cannot be deduced through brute-force methods without extensive computing power.

With the increase in size of hard drives and computer memory, the need for disk space and bandwidth still demands that a block-cipher algorithm be portable. DES, Triple DES, and the Advanced Encryption Standard (AES) all provide or have provided solutions that are secure and practical.

Implementation

Despite the controversy at the time, DES was implemented. It became the encryption standard of choice until the late 1990s, when it was broken when Deep Crack and distributed.net broke a DES key in 22 hours and 15 minutes.

8. A. Sorkin, "LUCIFER: A Cryptographic Algorithm," *Cryptologia*, 8(1), 22–35, 1984.

Later that year, a new form of DES called Triple DES, which encrypted the plaintext in three iterations, was published. It remained in effect until 2002, when it was superseded by AES.

Rivest, Shamir, and Adleman (RSA)

The release of DES also included the creation and release of Ron Rivest, Adi Shamir, and Leonard Adleman's encryption algorithm (RSA). Rivest, Shamir, and Adleman, based at the Massachusetts Institute of Technology (MIT), publicly described the algorithm in 1977. RSA is the first encryption standard to introduce (to public knowledge) the new concept of digital signing. In 1997 it was revealed through declassification of papers that Clifford Cocks, a British mathematician working for the U.K. Government Communications Headquarters (GCHQ), had, in 1973, written a paper describing this process. Assigned a status of top secret, the work had previously never seen the light of day. Because it was submitted in 1973, the method had been considered unattainable, since computing power at the time could not handle its methods.

Advanced Encryption Standard (AES or Rijndael)

AES represents one of the latest chapters in the history of cryptography. Once it became clear that neither DES nor its answer to its weaknesses, "Triple-DES," could carry encryption through to the twenty-first century, a decree went out from the National Institute of Standards and Technology (NIST) so that a new standard might be achieved. AES won out over the other standards for several reasons, and it is currently one of the most popular encryption standards. For people involved in any security work, its occurrence on the desktop is frequent. It also enjoys the free marketing and acceptance that it received when it was awarded the title of official cryptography standard in 2001.[9] This designation went into effect in May of the following year.

To a large degree, this part of the chapter is merely a rehashing/book report on the FIPS 197 standard, as this appears to be one of the more authoritative guides available, short of the authors themselves. It provides a few original examples, and some observations made by the author during his examination of the standard.

Similarly to DES, AES encrypts plaintext in a series of rounds, involves the use of a key and block sizes, and leverages substitution and permutation boxes. It differs from DES in the following respects:

9. U.S. FIPS PUB 197 (FIPS 197), November 26, 2001.

- It supports 128-bit block sizes.
- The key schedule is based on the S-box.
- It expands the key, not the plaintext.
- It is not based on a Feistel cipher.
- It is extremely complex.

The AES algorithms are to symmetric ciphers what a bowl of spaghetti is to the shortest distance between two points. Through a series of networked XOR operations, key substitutions, temporary variable transformations, increments, iterations, expansions, value swapping, S-boxing, and the like, a very strong encryption is created that, with modern computing, creates a cipher that itself is impossible to break. Like all ciphers, though, AES is only as strong as its weakest link, which is the password routine. This weakness will be explored toward the end of this part of the chapter.

Overview

Simply put, it works like this: First, the idea is to confuse the real message and the encrypted message. Like other encryption methods, it uses the XOR to do this. AES requires either 128, 192, or 256 bits to work; however, one must have a "key" with which to start. This might be a password, or a string of random numbers stored on a card, or any input derived from an unchanging, but unique thing, such as your retina. From there, the "key" needs to be both obfuscated and expanded to match the correct block size, and to be parceled up into the little packages, or blocks, that will be used in later operations of the encryption sequence. To accomplish this, a procedure called Password-Based Key Derivation Function (PBKDF2) is used.[10] Enciphering is achieved by then using an XOR and hashing the bits together again and again and again through a shift row offset. This effectively "shuffles the deck."

Second: Introduce diffusion by using a simple column transposition to rearrange the bits until they are no longer sensible as letters, and then hashing the bits using substitution (XOR). Furthermore, AES employs a key expansion and multiple rounds. For example, if you XOR a string and produce ciphertext, you have successfully obfuscated the message. If you want anyone to read it, just give them the key and they can reverse the XOR to get the correct text. The problem arises in portability: We want people to be able to decrypt our messages, but only if they have the pass key. This is where things get tricky, because we have to have a key that is long (128 or 256

10. RSA Laboratories Public-Key Cryptography Standards (PKCS) #5: Password-Based Cryptography Specification, Version 2.0. Network Working Group, B. Kaliski.

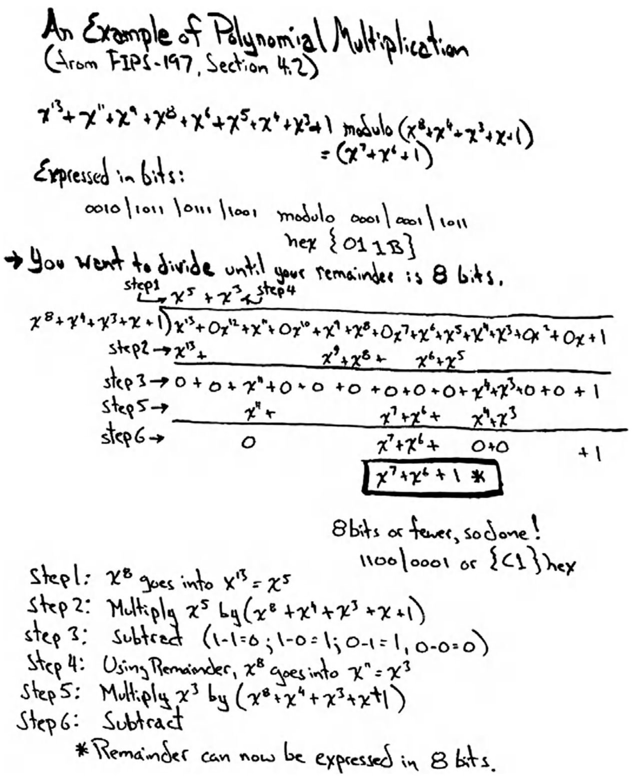

FIGURE 2.6 A handwritten example of polynomial expansion using the Rjindael/AES encryption algorithm.

bits) but that can be generated from a password that is reasonably short, so that we can remember it. Ultimately, this is the weakness of AES or actually the gateway into it, that is, the weak link.

The FIPS 197 standard canonicalizes the Rijndael algorithm Figure 2.6 [3,4], which is a symmetric block cipher with the capability to process blocks of 128 bits. To do this, it employs a multistep operation, enciphering the plaintext blocks using cipher keys with lengths of 128, 192, and 256 bits. The Rjindael algorithm possesses the ability to handle additional block sizes and key lengths, so while the capability exists, it is not part of the published FIPS 197 standard. This part of the chapter will cover the following topics

1. Some definitions that haven't been covered yet
2. A brief discussion about the notation and conventions used
3. Some mathematical properties of the algorithm
4. A brief discussion of how a password becomes a 128 (or longer) cipher key
5. A summary of the algorithm specification, including the key expansion, encryption, and decryption routines
6. Implementation issues
7. A step-by-step example from FIPS 197

The Basics of AES

The basic unit of encryption is the byte. If you read the beginning of this part of the chapter, then you already know that the cipher key must be in the form of 128, 192, or 256 bits, which is 16, 24, or 32 bytes, respectively. All bit values are 0 or 1; NULL values are disallowed. This of course may spark the question, "how then do NULL values get encrypted in BIT columns in a database?" In Microsoft SQL Server, an additional "hidden" column called a NULLmap exists; if a value is NULL, then it will be set to 1, otherwise, 0.[11]

AES encryption operates at the byte level, with each four bits represented (for convenience here) hexidecimally so that the following is true:

Binary value.hexidecimal value

For example, the value 1100 1101 would be represented as /xCD. XOR'd, with 0111 0110 /x76, would result in 1011 1011, or /xBB. (Note how obfuscating it is that two completely different pairs can XOR to the same value.)

6. HOW AES WORKS

The following describes each step of the cipher. It is a simplification, intended to provide a solid foundation for future study of the standard.

Bytes

Programmatically, in order to encipher the plaintext bits, the AES procedure requires that all of the bits be loaded and arranged into a two-dimensional array called the State. The State has four rows in it, and each row contains 4 bytes. This is a total of 16 bytes, or 128 bits.

NOTE: You might ask, "128 bits is great, but how did we go from a 32-bit password typed by a user to a 128-bit cipher key?" This can be done in a number of ways, and an industrious engineer may certainly write his own method for it, but for the readers of this book, check out the Password-Based Key Derivation Function (PBKDF2). This is a key derivation function that is part of RSA Laboratories Public Key Cryptography Standards. It replaces an earlier standard, PBKDF1, which could only produce derived keys up to 160 bits long.

The bytes are arranged in columns, so that the first column, first row (let's call it A1) has, right "beneath" it, A2, which would the second byte of the string to be encrypted. The actual FIPS standard has more dramatic

11. Paul S. Randall, Misconceptions around Null Bitmap Size. [http://www.sqlskills.com/BLOGS/PAUL/post/Misconceptions-around-null-bitmap-size.aspx], 2012.

notations for this, but essentially, what is happening is that in the State, bytes are referred to by row and by column, and they are loaded top to bottom, left to right. Each column of 4 bytes in the State is referred to as Word. Then it starts to do some math.

Math

The AES standard employs the mathematical operations of both addition and multiplication. Addition using the XOR has already been heavily covered in this chapter. For examples see Table 2.6. This standard also relies heavily on prime, or irreducible, polynomials to allow for the enciphering of the bits and to keep things nice and tidy in 128-bit buckets. It is important that, for reversibility, all of the multiplication operations, where strings of bits are represented as polynomials which can then be manipulated, allowing for the shifting of bits, remain irreducible.

For example, multiply together the primes 3, 7, and 17, and the resulting number is easily calculated as 357. By factoring it, you can easily derive the exact three numbers used in the original equation. Now multiply together 2, 8, and 16 and you get 256. Unfortunately, if you try to invert the operation, with the requirement that you want only three factors, you can arrive at 4, 4, and 16. Perhaps this is fine if you are writing a data-scrambling application, but an encryption utility is only as good as its ability to invert the cipher and decrypt the string. The AES standard outlines the mathematical polynomials used in the multiplication operations, and it defines them as being irreducible. For example, the purpose of one of the polynomial expressions in AES is to simply rotate the word, so that [b0, b1, b2, b3] is transformed into [b1, b2, b3, b0]. An irreducible polynomial is used so that, no matter what the input produces, the inverse operation performed against the output ciphertext yields the correct input. The cipher key becomes the *solution* for an extremely long equation, a solution that has such great uniqueness that it cannot be easily or quickly guessed.

Figure 2.5 provides an example of the actual mathematics behind the first expansion of the FIPS 197 standard. In it, each power of x takes a bit position, numbered as follows: 7654 3210. So, x^7 turns on the bit in position 7, x^6 in position 6, and x^0 (i.e., 1) takes the zeroth position. Hence, $x^7 + x^6 + 1 = 1100\ 0001$. This is why the remainder has to have x to the power of 7 or less, so it can be expressed in 8 bits. According to the standard, "these bytes are interpreted as finite field elements using a polynomial representation." Frequently, to conserve space or just to make things look less ridiculously *binary*, a hexadecimal value may be used. Table 2.10 demonstrates the conversion of binary to base 16, AKA "hexidecimal."

TABLE 2.10 Binary and its Hexadecimal Equivalents.

Binary	HEX
0000	0
0001	1
0010	2
0011	3
0100	4
0101	5
0110	6
0111	7
1000	8
1001	9
1010	a
1011	b
1100	c
1101	d
1110	e
1111	f

In the Beginning

In the beginning, there are bits, and the bits have a physicality that is linear. That is, they are all lined up in one continuous string on the disk, unless the disk is fragmented, but that's another story. You should always keep your disks defragmented. Fragmentation is bad and will impact the performance of processing data for encryption. If, for example, you are encrypting thousands of files in a particular folder on the disk, and the files are all over the place, it will perform poorly. I digress. When a program that executes AES encryption gets its byte on your bits, the first thing it does is load them into a series of arrays called the State. This particular state is good because it will not take all of your money or tell you that you didn't pay enough taxes last year. What it will do is provide a place where many different operations can be executed to better encrypt your data using a 128-bit cipher key. For the purpose of convenience, though AES can handle 192- and 256-bit encryption as well, the author simply refers to the 128-bit model. All operations are performed against this two-dimensional array of bytes called the State, which contains four rows of bytes; each row holds Nb bytes, where Nb is the block length (128, 192,256) divided by 32.

The State array, s, has two indices. Denoted by the symbol s, each individual byte has two indices, with its row number r in the range $0 \leq r < 4$ and its column number c in the range $0 \leq c < Nb$. This allows an individual byte of the State to be referred to as either sr,c or s[r,c]. AES requires Nb = 4, so that $0 \leq c < 4$. In other words, if you think of an input, a state, and an output array as being the program product line, each array will be the exact same size. AES does explode the size of the output file.

Rounds

The number of rounds to be executed by the algorithm depends on the key size. Nr = 10 when Nk = 4, Nr = 12 when Nk = 6, and Nr = 14 when Nk = 8. AES, for encipherment, uses a "round" methodology where each round consists of four steps:

1. byte substitution driven by a substitution table (S-box)
2. the shifting of rows in the State array by an offset
3. bit and byte shuffling within each column of the State
4. adding a Round Key to the State

These transformations (and their inverses) are explained in detail in Sections 5.1.1–5.1.4 and 5.3.1–5.3.4 of FIPS 197. Details, and even code samples, can be found in the standard. This example is drawn directly from the standard and details the operations of the cipher itself. Essentially, the following functions are described in the standard and can be understood to be the steps taken in each encryption round. The number of rounds depends on the size of the encryption key:

1. SubBytes(state)
2. ShiftRows(state)
3. MixColumns(state)
4. AddRoundKey(state, w[round*Nb, (round + 1)*Nb-1])

By now, the reader of this text should realize that public standards such as FIPS-197 contain a wealth of information and that the chapters in this book can merely provide (hopefully) the background needed to lend clarity to the material. This part of the chapter is, of course, no substitution for actually reading and adhering to the standard as published.

Finally, it is conceivable that, with so complex a series of operations, a computer file and block could be combined in such a way as to produce all zeroes. Theoretically, the AES cipher could be broken by solving massive quadratic equations that take into consideration every possible vector and solve 8000 quadratic equations with 1600 binary unknowns. This sort of an attack is called an *algebraic attack*, and, where traditional methods such as differential or differential cryptanalysis fail, it is suggested that the strength in AES lies in the current inability to solve supermultivariate quadratic equations with any sort of efficiency.

Reports that AES is not as strong as it should be are at this time likely to be overstated and inaccurate because anyone can present a paper that is dense and difficult to understand and claims to achieve the incredible. It is unlikely that, any time in the near or maybe not-so-near future (this author hedges his bets), AES will be broken using multivariate quadratic polynomials in thousands of dimensions. Mathematica is very likely one of the most powerful tools that can solve quadratic equations, and it is still many years away from being able to perform this feat.

Ultimately, AES's biggest drawback is that a user can trigger an encryption using a password of his or her choice. Unfortunately, most people choose passwords that are not very strong—they want something they will *remember*. Many is the IT tech who lost his password and rendered systems inalterable. Many, too, is the sinister communication that may pass from an employee to a future employer, or a competitor with whom he has become friendly, and has decided to pass secrets. Intellectual property (IP) tort is a very real facet of litigation, and to this end, large consultancies that deal in computer forensics and e-discovery host rack upon rack of devices that are designed specifically to decrypt files that have been encrypted using AES encryption. They do this not by attacking the algorithm, but by attacking using brute force. *Hash tables*, or rainbow tables, are basically a list of all the known hash values of common (and not so common) passwords. For example, one might take every known phone number in the United States and create a table of all of their known hashes. One might also create one of every known child's name and parse that into the hash tables. For example, a phone number of 847-555-5555 might be combined with the name "Ethan" (who is known to live at a certain address, 233 TreeView), into a password of 233Ethan5555tree! (I added the exclamation point to be even more "secure"...). In fact, some of the largest consultancy firms who manage large litigations have constructed exactly this sort of database of rainbow tables, and they are generating more and more hashes each day. Programs that provide entire disk encryption are the bane of both law enforcement and litigation.

Brute force attacks are the only way to crack in when no key can (or will) be produced. Why do rainbow tables work? The spectrum of possible passwords that people may choose to use *because they can remember* them is much smaller than the total number of possible passwords that exist. By leveraging as much as 7 terabytes of rainbow tables against an encrypted body, the estimated success rate of cracking files, spectuively, could be as high as 60 to 70 percent. This is a quite horrible statistic for an encryption algorithm that is supposedly "unbreakable." So perhaps the one take -away from this

An Agenda for Action for Selecting the Cryptographic Process Activities

The following high-level checklist questions should be addressed in determining the appropriate cryptographic mechanisms, policies, and procedures for a system (check all tasks completed):

_____**1.** How critical is the system to the organization's mission, and what is the impact level?

_____**2.** What are the performance requirements for cryptographic mechanisms (communications throughput, processing latency)?

_____**3.** What intersystem and intrasystem compatibility and interoperability requirements need to be met by the system (algorithm, key establishment, and cryptographic and communications protocols)?

_____**4.** What are the security/cryptographic objectives required by the system (content integrity protection, source authentication required, confidentiality, availability)?

_____**5.** For what period of time will the information need to be protected?

_____**6.** What regulations and policies are applicable in determining what is to be protected?

_____**7.** Who selects the protection mechanisms that are to be implemented in the system?

_____**8.** Are the users knowledgeable about cryptography, and how much training will they receive?

_____**9.** What is the nature of the physical and procedural infrastructure for the protection of cryptographic material and information (storage, accounting and audit, logistics support)?

_____**10.** What is the nature of the physical and procedural infrastructure for the protection of cryptographic material and information at the facilities of outside organizations with which cryptographically protected communications are required (facilities and procedures for protection of physical keying material)?

writing is that there is still room for improvement; a truly unbreakable system still does not exist, and while the algorithm of AES cannot be successfully attacked through decomposition of the cipher text, any system that fails to take into account EVERY attack vector will, ultimately, be no stronger than its weakest link.

Finally, let's briefly look at the process that is used to select cryptographic mechanisms. This is similar to the process used to select any IT mechanism.

7. SELECTING CRYPTOGRAPHY: THE PROCESS

The cryptography selection process is documented in the system development life cycle (SDLC) model. An organization can use many SDLC models to effectively develop an information system. A traditional SDLC is a linear sequential model. This model assumes that the system will be delivered near the end of its development life cycle. Another SDLC model uses prototyping, which is often used to develop an understanding of system requirements without developing a final operational system. More complex models have been developed to address the evolving complexity of advanced and large information system designs. The SDLC model is embedded in any of the major system developmental approaches:

- Waterfall: The phases are executed sequentially.
- Spiral: The phases are executed sequentially, with feedback loops to previous phases.
- Incremental development: Several partial deliverables are constructed, and each deliverable has incrementally more functionality. Builds are constructed in parallel, using available information from previous builds. The product is designed, implemented, integrated, and tested as a series of incremental builds.
- Evolutionary: There is re-planning at each phase in the life cycle, based on feedback. Each phase is divided into multiple project cycles with deliverable measurable results at the completion of each cycle.

Security should be incorporated into all phases, from initiation to disposition, of an SDLC model. The goal of the selection process is to specify and implement cryptographic methods that address specific agency/organization needs.

Prior to selecting a cryptographic method, an organization should consider the operational environment, the application requirements, the types of services that can be provided by each type of cryptography, and the cryptographic objectives that must be met when selecting applicable products. Based on the requirements, several cryptographic methods may be required. For example, both symmetric and asymmetric cryptography may be needed in one system, each performing different functions (symmetric encryption, and asymmetric digital signature and key establishment). In addition, high-level checklist questions should be addressed in determining the appropriate cryptographic mechanisms, policies, and procedures for a system (see checklist: An Agenda for Action for Selecting the Cryptographic Process Activities).

8. SUMMARY

Today's information technology security environment consists of highly interactive and powerful computing devices and interconnected systems of systems across global networks where organizations routinely interact with industry, private citizens, state and local governments, and the governments of other nations. Consequently, both private and public sectors depend on information systems to perform essential and mission-critical functions. In this environment of increasingly open and interconnected systems and networks, network and data security are essential for the optimum use of this information technology. For example, systems that carry out electronic financial transactions and electronic commerce (e-commerce) must protect against unauthorized access to confidential records and the unauthorized modification of data.

Thus, in keeping with the preceding, this chapter provided guidance to organizations on how to select cryptographic controls for protecting sensitive information. However, to provide additional information, products of other standards organizations (the American National Standards Institute and International Organization for Standardization) were briefly discussed.

This chapter was also intended for security individuals responsible for designing systems, and for procuring, installing, and operating security products to meet identified security requirements. This chapter may be used by:

- A manager responsible for evaluating an existing system and determining whether cryptographic methods are necessary.
- Program managers responsible for selecting and integrating cryptographic mechanisms into a system.
- A technical specialist requested to select one or more cryptographic methods/techniques to meet a specified requirement.
- A procurement specialist developing a solicitation for a system or network that will require cryptographic methods to perform security functionality.

In other words, this chapter provided the preceding individuals with sufficient information that allowed them to make informed decisions about the cryptographic methods that met their specific needs to protect the confidentiality, authentication, and integrity of data that is transmitted and/or stored in a system or network. In addition, this primer also provided information on selecting cryptographic controls and implementing the controls in new or existing systems.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and the optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? For most information technology occupations, knowledge of cryptography is a very large part of a broader skill set, and is generally limited to relevant application.
2. True or False? Cryptography is built on one overarching premise: the need for a cipher that can reliably, and portably, be used to encrypt text so that, through any means of cryptanalysis—differential, deductive, algebraic, or the like—the ciphertext can be undone with any available technology.
3. True or False? In effect, the Vernam stream cipher and "one-time pad" ciphers are very different – in fact, Vernam later co-invented it.
4. True or False? DES used a 64-bit block cipher combined with a mode of operation based on cipher-block chaining (CBC) called the *Feistel function*.
5. True or False? The cryptography selection process is documented in the system development life cycle (SDLC) model.

Multiple Choice

1. In essence, computer-based cryptography is the art of creating a form of communication that embraces the following precepts, except which two?
   A. Can be readily misunderstood by the intended recipients
   B. Cannot be understood by unintended recipients
   C. Can be understood by unintended recipients
   D. Can be readily understood by the intended recipients
   E. Can be adapted and changed easily with relatively small modifications, such as a changed pass phrase or word
2. What is known as the method of encryption?
   A. Plaintext
   B. Clear text
   C. Ciphertext
   D. Cryptogram
   E. Cipher
3. Decryption methods often rely on understanding the context of the:
   A. cipher
   B. ciphertext
   C. shift cipher
   D. cryptogram
   E. cryptographic algorithms
4. The amount of ciphertext needed to successfully break a cipher is known as:
   A. Benford's Law.
   B. chi-square statistic.

   C. polyalphabetic cipher.
   D. Kerckhoff's principle.
   E. unicity distance.
5. One method of teasing out the frequency patterns is through the application of some sort of mathematical formula to test a hypothesis against reality. What test is perhaps one of the most commonly used:?
   A. Inferential statistics test
   B. Chi-square test
   C. Statistical test
   D. Random binary stream cipher test
   E. Block cipher test

EXERCISE

Problem

OpenSSL has a trick in it that mixes uninitialized memory with the randomness generated by the OS's formal generator. The standard idea here is that it is good practice to mix different sources of randomness into your own source. Modern operating systems take several random things like disk drive activity and net activity and mix the measurements into one pool, and then run it through a fast hash to filter it. Cryptoplumbing on the other hand, of necessity involves lots of errors and fixes and patches. Bug-reporting channels are very important, and apparently this was used. A security team found the bug with an analysis tool. It was duly reported up to OpenSSL, but the handover was muffed. The reason it was muffed was that it wasn't obvious what was going on. And the reason it wasn't obvious is that code was too clever for its own good. It tripped up the analysis tool; the programmers; and, the fix did not alert the OpenSSL programmers. Complexity is always the enemy in security code. So, with the preceding in mind, what would you do as a risk manager to fix the problem?

Hands-On Projects

Project

What is the basic method for using the output of a random bit generator?

Case Projects

Problem

How would an organization go about generating key pairs for asymmetric key algorithms?

Optional Team Case Project

Problem

How would an organization go about generating keys for symmetric key algorithms?

Chapter 3

Detecting System Intrusions

Almantas Kakareka, CISSP, GSNA, GSEC, CEH
Demyo, Inc.

1. INTRODUCTION

First things first: Detecting system intrusion is not the same as Intrusion Detection System/Intrusion Prevention System (IDS/IPS). We want to detect system intrusion once attackers pass all defensive technologies in the company (such as IDS/IPS mentioned above), full-packet capture devices with analysts behind them, firewalls, physical security guards, and all other preventive technologies and techniques. Many preventative technologies are using blacklisting [1] most of the time, and thus that's why they fail. Blacklisting is allowing everything by default and forbidding something that is considered to be malicious. So, for the attacker, it is a challenge to find yet another way to bypass the filter. It is so much harder to circumvent a whitelisting system.

2. MONITORING KEY FILES IN THE SYSTEM

What are key files on the server? In the Linux machine it will be /etc/passwd, /etc/shadow, just to mention a few. Let's take a look at an example of /etc/shadow file below:

```
# cat /etc/shadow
root:$6$OFny79f/$LC5hcqZXNYKachPKheRh5WkeTpa/
zO3y8OX3EUHrFkrFQAdLUTKwGjLPSdZ9uhwJQ9GmChLvbh
PRbPw7lDTg90:15231:0:99999:7:::
daemon:x:15204:0:99999:7:::
bin:x:15204:0:99999:7:::
sys:x:15204:0:99999:7:::
www-data:15204:0:99999:7:::
<snip>
pulse:j:15204:0:99999:7:::
rtkit:j:15204:0:99999:7:::
festival:j:15204:0:99999:7:::
postgres:!:15204:0:99999:7:::
apache:$6$LqrWIgqp
$jdq1exB2GiBFgLL9kDlDkks30azWBJ1/mDU.
to84mHn6nmzUzV7iHiMXK7rVm8.
p1MmaNKg9Yyu7rywOOr5VX.:15452:0:99999:7:::
```

What is wrong with the preceding file? If you take a look at users listed in this file, you will notice that an apache user has a hash value attached to it. Typically, apache service never has any hash associated with it. If there is a hash for a use in this file, that means this user has a password associated with it and is able to log in via Secure Shell (SSH). What happens here is that a hacker made a brand-new account and is trying to camouflage it with a valid system user/process.

One of the ways to monitor changes in the file system is to implement LoggedFS. This particular file system logs everything that happens inside the file system. It is easily configurable via Extensible Markup Language (XML) files to fit your needs [2]. An example of a LoggedFS configuration file is as follows:

```
<?xml version="1.0" encoding="UTF-8"?>
<loggedFS logEnabled="true"
printProcessName="true">
<includes>
<include extension=".j" uid="j" action=".j"
retname=".j"/>
</includes>
<excludes>
<exclude extension=".j\.bak$" uid="j" action=".
j" retname="SUCCESS"/>
<exclude extension=".j" uid="1000" action=".j"
retname="FAILURE"/>
<exclude extension=".j" uid="j"
action="getattr" retname=".j"/>
</excludes>
</loggedFS>
```

The preceding configuration can be used to log everything except if it concerns a *.bak file, or if the uid is 1000, or if the operation is getattr.

Files Integrity

File integrity monitoring (FIM) is an internal control or process that performs the act of validating the integrity of

the operating system and application software files using a verification method between the current file state and the known, good baseline. This comparison method often involves calculating a known cryptographic checksum of the file's original baseline and comparing that with the calculated checksum of the current state of the file. Other file attributes can also be used to monitor integrity.

Generally, the act of performing file integrity monitoring is automated, using internal controls such as an application or a process. Such monitoring can be performed randomly, at a defined polling interval, or in real time.

3. SECURITY OBJECTIVES

Changes to configurations, files, and file attributes across the IT infrastructure are common; but hidden within a large volume of daily changes can be the few that impact the file or configuration integrity. These changes can also reduce security posture and in some cases may be leading indicators of a breach in progress. Values monitored for unexpected changes to files or configuration items include:

- Credentials
- Privileges and security settings
- Content
- Core attributes and size
- Hash values
- Configuration values

Many open-source and commercial software products are available that perform file integrity monitoring:

- CimTrak
- OSSEC
- Samhain
- Tripwire
- Qualys
- nCircle
- Verisys
- AIDE [3]

An nCircle file integrity monitor panel is shown in Figure 3.1.

There Is Something Very Wrong Here

One bit or one symbol in the output may make the difference between war and peace, friend and foe, compromised and clean system. Let's take a look at the example

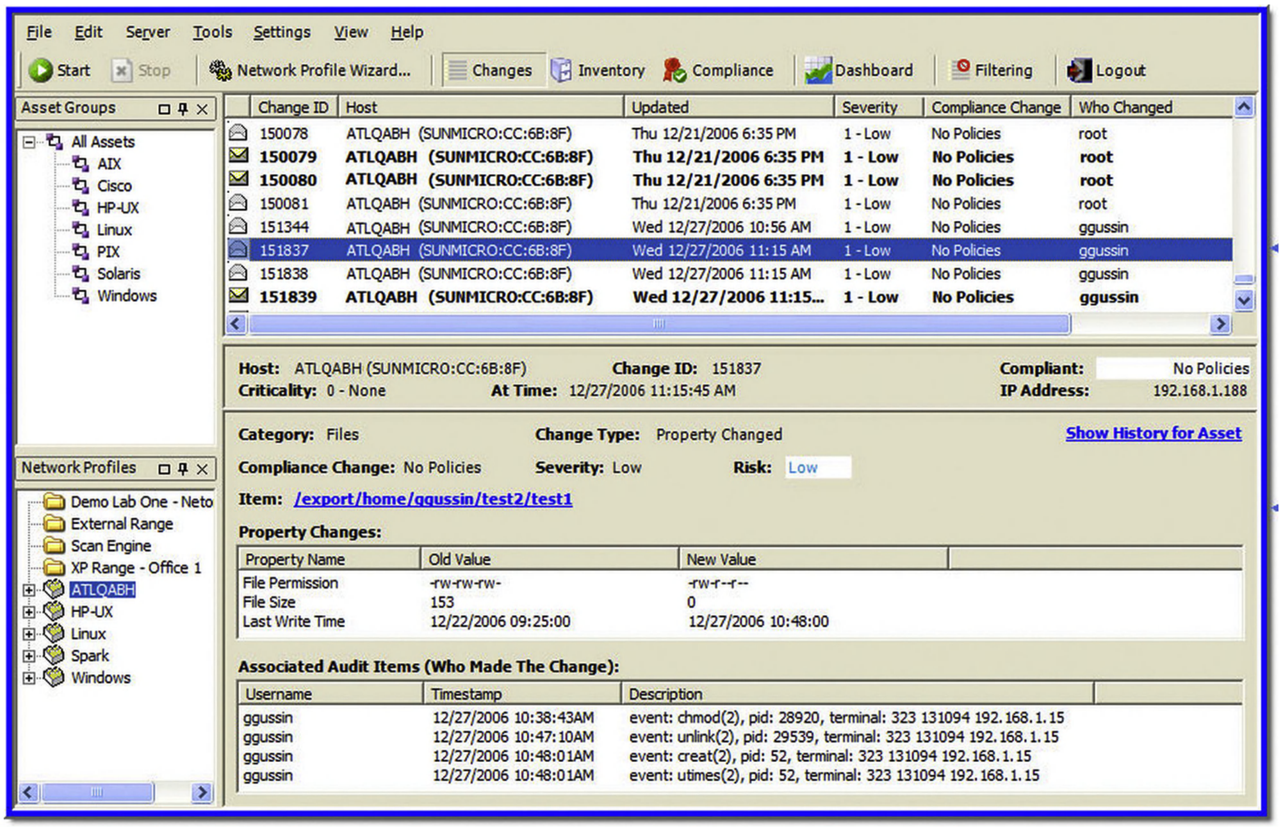

FIGURE 3.1 nCircle file integrity monitor panel.

that is shown in Figure 3.2: What appears to be wrong with this screenshot?

For those who don't see the wrong symbol here, I will give you a hint. It is a command to list files in the directory; switch –h is for listing output in human readable format (megabytes will be megabytes and gigabytes will be gigabytes, not 1 073 741 824 bytes). Switch –l makes a list of files, once again to be easily readable by humans. Now, we are coming to the main piece of information here: Switch –a output will include directory entries whose names begin with a dot (.). A common hacker's technique is to hide within legitimate file names or within somewhat legitimate names. In this case, the hacker has a directory on the system, which is named '. ' ; this is the main issue here. In normal output, you should see one single dotted directory; in this case, we see two single dotted directories, which should raise big red flags for you. A change to this hidden directory is made by issuing command cd '. '. Just make sure there is a space after dot.

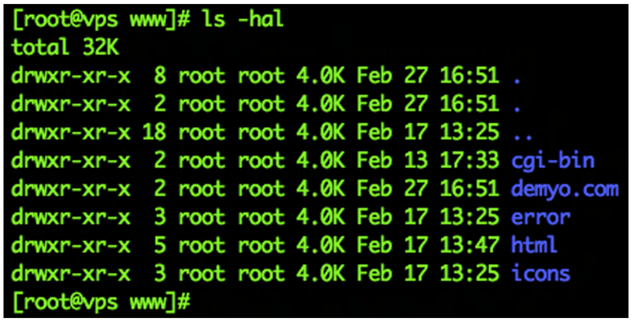

FIGURE 3.2 The wrong symbol.

So, that's why we want to use ls –hal with switch 'a' all the time: because we want to see hidden directories and hidden files. It is pretty common to have these hidden directories in common places, such as: /root, /var/www, /home, and others.

Additional Accounts on the System

Every account on the system should be accounted for. If there are accounts whose source nobody knows, that may mean the system is compromised. Sometimes, IT administrators forget to disable old accounts for people who have left the company; some of these accounts may be active for months and even years. This is an unnecessary risk that is introduced by poor IT administrators' management. A good practice is to disable an employee's account before the exit interview. After a compromise, hackers may create a new account on the server and try to mimic some legitimate accounts that should exist. An example of additional account Distributed Brokered Networking (DBNET) is shown in Figure 3.3.

Timestamps

A timestamp is a sequence of characters or encoded information that identifies when a certain event occurred, usually giving date and time of day; it is sometimes accurate to a small fraction of a second. The term is derived from the rubber stamps that were used in nineteenth-century offices to stamp the current date and time (in ink) on paper documents and to record when the document was received. A common example of this type of timestamp is a postmark on a letter. However, in modern times, usage

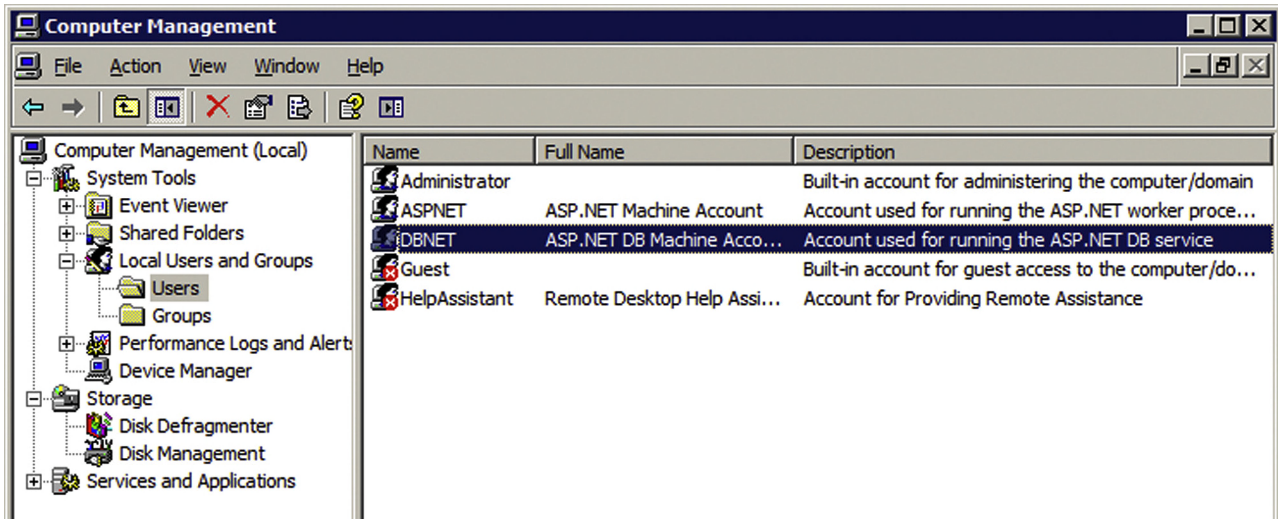

FIGURE 3.3 Additional account DBNET.

of the term has expanded to refer to the digital date and time the information was attached to digital data. For example, computer files contain timestamps that tell when the file was last modified; digital cameras add timestamps to the pictures they take, recording the date and time the picture was taken.

A timestamp is the time an event is recorded by a computer, not the time of the event itself. In many cases, the difference may be inconsequential: The time at which an event is recorded by a timestamp (entered into a log file) should be close to the time of the event.

The sequential numbering of events is sometimes called timestamping. The practice of recording timestamps in a consistent manner along with the actual data is called timestamping. This data is usually presented in a consistent format, allowing for the easy comparison of two different records and tracking progress over time.

Timestamps are typically used for logging events or in a sequence of events (SOE), in which case each event in the log or SOE is marked with a timestamp. In file systems, the timestamp may mean the stored date/time when a file is created or modified.

Let's say you have a lot of folders and executable files in the C:/Windows/System32 directory. All of them pretty much match operating system (OS) installation date and time, but there is one folder that does not match OS installation time. Could there be a problem? This executable might be just some additional software that was installed later on the system, or it also might be malware hiding in this directory. Windows malware just loves this folder! The folder shown in Figure 3.4 was modified in a different month from all the others.

Hidden Files and Directories

A hidden file is not normally visible when examining the contents of the directory in which it resides. Likewise, a hidden directory is normally invisible when examining the contents of the directory in which it resides.

A file is a named collection of related information that appears to the user as a single, contiguous block of data and that is retained in storage. Storage refers to computer devices or media that can retain data for relatively long periods of time (years or decades), such as hard disk drives (HDDs), Compact Disk—Read Only Memory (CDROMs), and magnetic tape; this contrasts with memory, which retains data only as long as the data is in use or the memory is connected to a power supply.

A directory (also sometimes referred to as a folder) can be conveniently viewed as a container for files and other directories. In Linux and other Unix-like operating systems, a directory is merely a special type of file that associates file names with a collection of metadata (data about the files). Likewise, a link is a special type of file that points to another file (which can be a directory). Thus, it is somewhat redundant to use phrases such as hidden files and directories; however, they are descriptive

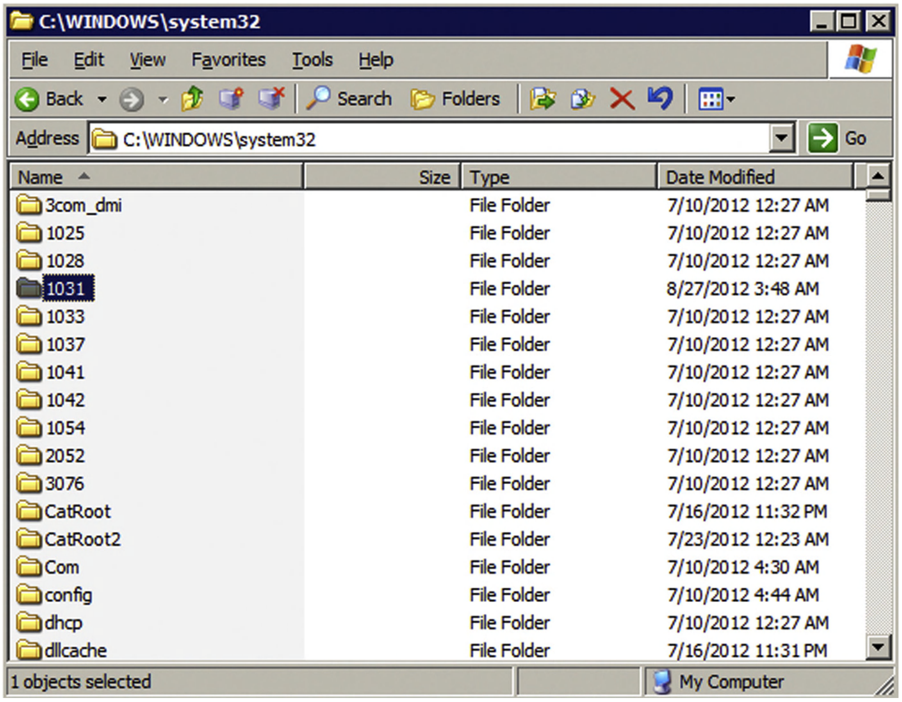

FIGURE 3.4 Folder modification.

and convenient, and thus they are frequently used. More precise terms are hidden file system objects and hidden items.

Hidden items on Unix-like operating systems are easily distinguishable from regular (nonhidden) items because their names are prefixed by a period (a dot). In Unix-like operating systems, periods can appear anywhere within the name of a file, directory, or link, and they can appear as many times as desired. However, usually, the only time that they have special significance is when they are used to indicate a hidden file or directory.

In the Microsoft Windows operating systems, whether or not a file system object is hidden is an attribute of the item, along with such things as whether the file is read-only and a system file (a file that is critical to the operation of the operating system). Changing the visibility of such items is accomplished using a multistep procedure.

Unix-like operating systems provide a larger set of attributes for file system objects than do the Microsoft Windows operating systems, including a system of permissions, which control which user(s) have access to each such object for reading, writing and executing. However, whether or not objects are hidden is not among the attributes. Rather, it is merely a superficial property that is easily changed by adding or removing a period from the beginning of the object name.

Many operating systems and application programs routinely hide objects in order to reduce the chances of users accidentally damaging or deleting critical system and configuration files. Hiding objects can also be useful for reducing visual clutter in directories, thereby making it easier for users to locate desired files and subdirectories.

Another reason to hide file system objects is to make them invisible to casual snoopers. Although it is very easy to make hidden files and directories visible, the great majority of computer users are not even aware that such files and directories exist (nor need they be) [4].

4. 0DAY ATTACKS

About 90 percent of all successful compromises are made via known flaws, so 0day attacks are not that common. A zero-day attack or threat is an attack that exploits a previously unknown vulnerability in a computer application, meaning that the attack occurs on “day zero” of awareness of the vulnerability. This means that the developers have had zero days to address and patch the vulnerability. 0day exploits (actual software that uses a security hole to carry out an attack) are used or shared by attackers before the developer of the target software knows about the vulnerability.

Attack Vectors

Malware writers are able to exploit zero-day vulnerabilities through several different attack vectors. Web browsers are a particular target because of their widespread distribution and usage. Attackers can also send email attachments, which exploit vulnerabilities in the application opening the attachment. Exploits that take advantage of common file types are listed in databases such as United States Computer Emergency Readiness (US-CERT). Malware can be engineered to take advantage of these file-type exploits to compromise attacked systems or steal confidential data such as banking passwords and personal identity information.

Vulnerability Window

Zero-day attacks occur during the vulnerability window that exists in the time between when vulnerability is first exploited and when software developers start to develop and publish a counter to that threat. For viruses, Trojans, and other zero-day attacks, the vulnerability window typically follows this time line:

- The developer creates software containing an unknown vulnerability.
- The attacker finds the vulnerability before the developer does.
- The attacker writes and distributes an exploit while the vulnerability is not known to the developer.
- The developer becomes aware of the vulnerability and starts developing a fix.

Measuring the length of the vulnerability window can be difficult, as attackers do not announce when the vulnerability was first discovered. Developers may not want to distribute data for commercial or security reasons. They also may not know if the vulnerability is being exploited when they fix it, and so they may not record the vulnerability as a zero-day attack. However, it can be easily shown that this window can be several years long. For example, in 2008, Microsoft confirmed vulnerability in Internet Explorer, which affected some versions that were released in 2001. The date the vulnerability was first found by an attacker is not known; however, the vulnerability window in this case could have been up to seven years.

Discovery

A special type of vulnerability management process focuses on finding and eliminating zero-day weaknesses. This unknown vulnerability management life cycle is a security and quality assurance process that aims to ensure the security and robustness of both in-house and

third-party software products by finding and fixing unknown (zero-day) vulnerabilities. The unknown vulnerability management process consists of four phases: analyze, test, report, and mitigate.

- Analyze: This phase focuses on attack surface analysis.
- Test: This phase focuses on fuzz testing the identified attack vectors.
- Report: This phase focuses on reproduction of the found issues to developers.
- Mitigate: This phase looks at the protective measures explained below.

Protection

Zero-day protection is the ability to provide protection against zero-day exploits. Zero-day attacks can also remain undetected after they are launched.

Many techniques exist to limit the effectiveness of zero-day memory corruption vulnerabilities, such as buffer overflows. These protection mechanisms exist in contemporary operating systems such as Windows 7, Microsoft Windows Vista, Apple's Mac OS X, recent Oracle Solaris, Linux and possibly other Unix and Unix-like environments; Microsoft Windows XP Service Pack 2 includes limited protection against generic memory corruption vulnerabilities. Desktop and server protection software also exists to mitigate zero-day buffer overflow vulnerabilities.

"Multiple layers" provides service-agnostic protection and is the first line of defense should an exploit in any one layer be discovered. An example of this for a particular service is implementing access control lists in the service itself, restricting network access to it via local server firewalling (IP tables), and then protecting the entire network with a hardware firewall. All three layers provide redundant protection in case a compromise in any one of them occurs.

The use of port knocking or single-packet authorization daemons may provide effective protection against zero-day exploits in network services. However, these techniques are not suitable for environments with a large number of users.

Whitelisting effectively protects against zeroday threats. Whitelisting will only allow known good applications to access a system, and so, any new or unknown exploits are not allowed access. Although whitelisting is effective against zero-day attacks, an application "known" to be good can in fact have vulnerabilities that were missed in testing. To bolster its protection capability, it is often combined with other methods of protection such as a host-based intrusion-prevention system or a blacklist of virus definitions, and it can sometimes be quite restrictive to the user. Also, keeping the computer's software up to date is very important, and it does help.

Users need to be careful when clicking on links or opening email attachments with images or PDF files from unknown users. This is how many cyber criminals deceive users, by pretending they are something they are not and gaining the user's trust. In addition, sites should be utilized with Secure Socket Layer (SSL), which secures the information being passed between the user and the visited site.

Ethics

Differing views surround the collection and use of zero-day vulnerability information. Many computer security vendors perform research on zero-day vulnerabilities in order to better understand the nature of vulnerabilities and their exploitation by individuals, computer worms, and viruses. Alternatively, some vendors purchase vulnerabilities to augment their research capacity. While selling and buying these vulnerabilities is not technically illegal in most parts of the world, there is much controversy over the method of disclosure. A recent German decision to include Article 6 of the Convention on Cybercrime and the European Union (EU) Framework Decision on Attacks against Information Systems may make selling or even manufacturing vulnerabilities illegal.

Most formal efforts follow some form of disclosure guidelines or the more recent Office of Information Systems (OIS) Guidelines for Security Vulnerability Reporting and Response. In general, these rules forbid the public disclosure of vulnerabilities without notification to the developer and adequate time to produce a patch.

5. GOOD KNOWN STATE

When attackers compromise a system, what is the very first thing they do? They install different backdoors and as many as possible. So, if some backdoor was found on the system and it was deleted, it does not mean the system is clean. It is much safer to restore the system to a good known state; typically it is done via OS reinstallation. Big companies typically have a gold image for their systems. They use a gold image to quickly wipe any infected machine and reinstall OS with all of its updates, and software at once. On Linux systems, the software called System Imager is capable of doing many Linux installations at once.

System Imager is software that makes the installation of Linux to numerous similar machines relatively easy.

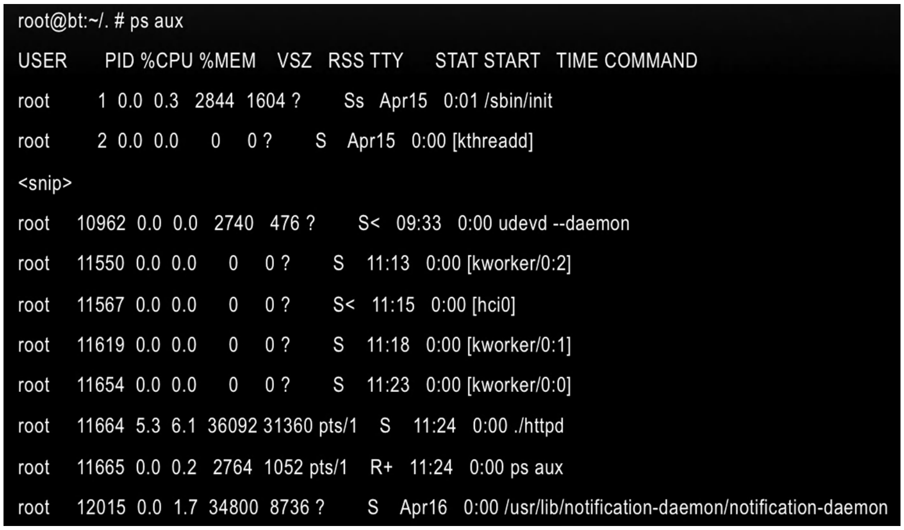

FIGURE 3.5 The running process list.

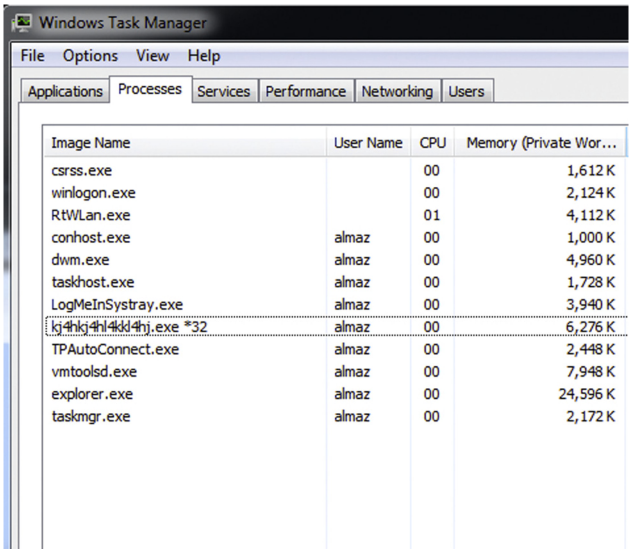

FIGURE 3.6 Strange file names.

It makes software distribution, configuration, and operating system updates easy, and it can also be used for content distribution [5].

Monitoring Running Processes in the System

What is wrong with the running process list in the following Linux system, as shown in Figure 3.5?

The process ./httpd should catch a security professional's eye. Dot slash at the beginning indicates it was launched locally from the directory. Processes on the servers typically are not launched locally from their directories. The attacker has launched a process and is trying to hide by renaming his software to legitimate-looking software typically found on the server.

Files with Weird Names

Malware frequently makes weird-looking file names. An example of this is shown in the Windows Task Manager screen in Figure 3.6.

The file: kj4hkj4hl4kkl4hj.exe shown in Figure 3.6 is running in memory. This should be a first indicator that something funky is going on in the system. Windows updates create random named temporary folders and should not be confused with malware.

6. ROOTKITS

A rootkit is a stealthy type of malicious software designed to hide the existence of certain processes or programs from normal methods of detection, and enables continued privileged access to a computer. The term *rootkit* is a concatenation of the word "root" (the traditional name of the privileged account on Unix operating systems) and the word "kit" (which refers to the software components that implement the tool). The term *rootkit* has negative connotations through its association with malware.

Rootkit installation can be automated, or an attacker can install it once they've obtained root or Administrator access. Obtaining this access is either a result of a direct attack on a system (exploiting a known vulnerability), or by having obtained a password (either by cracking,

privilege escalation, or through social engineering). Once installed, it becomes possible to hide the intrusion as well as to maintain privileged access. Like any software, they can have a good purpose or a malicious purpose. The key is the root/administrator access. Full control over a system means that existing software can be modified, including software that might otherwise be used to detect or circumvent it.

Rootkit detection is difficult because a rootkit may be able to subvert the software that is intended to find it. Detection methods include using an alternative and trusted operating system, behavioral-based methods, signature scanning, difference scanning, and memory dump analysis. Removal can be complicated or practically impossible, especially in cases where the rootkit resides in the kernel; reinstallation of the operating system may be the only available solution to the problem. When dealing with firmware rootkits, removal may require hardware replacement or specialized equipment.

Kernel-Level Rootkits

Kernel-mode rootkits run with the highest operating system privileges (Ring 0) by adding code or replacing portions of the core operating system, including both the kernel and associated device drivers. Most operating systems support kernel-mode device drivers, which execute with the same privileges as the operating system itself. As such, many kernel-mode rootkits are developed as device drivers or loadable modules, such as loadable kernel modules in Linux or device drivers in Microsoft Windows. This class of rootkit has unrestricted security access but is more difficult to write. The complexity makes bugs common, and any bugs in code operating at the kernel level may seriously impact system stability, leading to the discovery of the rootkit. One of the first widely known kernel rootkits was developed for Windows NT 4.0 and released in the *Phrack* magazine in 1999 [6].

Kernel rootkits can be especially difficult to detect and remove because they operate at the same security level as the operating system itself and are thus able to intercept or subvert the most trusted operating system operations. Any software, such as antivirus software, running on the compromised system is equally vulnerable. In this situation, no part of the system can be trusted.

A rootkit can modify data structures in the Windows kernel using a method known as direct kernel object modification (DKOM). This method can hook kernel functions in the System Service Descriptor Table (SSDT), or modify the gates between user mode and kernel mode, in order to cloak itself. Similarly for the Linux operating system, a rootkit can modify the system call table to subvert kernel functionality. It's not uncommon for a rootkit to create a hidden, encrypted file system in which it can hide other malware or original copies of files it has infected.

Operating systems are evolving to counter the threat of kernel-mode rootkits. For example, 64-bit editions of Microsoft Windows now implement mandatory signing of all kernel-level drivers in order to make it more difficult for untrusted code to execute with the highest privileges in a system.

Userland Rootkits

User-mode rootkits run in ring 3, along with other applications as user, rather than low-level system processes. They have a number of possible installation vectors to intercept and modify the standard behavior of application programming interfaces (APIs). Some inject a dynamically linked library (such as a .dll file on Windows, or a .dylib file on Mac OS X) into other processes and are thereby able to execute inside any target process to spoof it; others with sufficient privileges simply overwrite the memory of a target application. Injection mechanisms include:

- Use of vendor-supplied application extensions. For example, Windows Explorer has public interfaces that allow third parties to extend its functionality.
- Interception of messages
- Debuggers
- Exploitation of security vulnerabilities
- Function hooking or patching of commonly used APIs, for example, to mask a running process or file that resides on a file system

Rootkit Detection

There are a lot of software for rootkit searches that are meant to be run on a live system. One of many examples would be the software "rootkit hunter".

7. LOW HANGING FRUIT

Do you have to run faster than a cheetah? Not necessarily. You just have to be running faster than your friend, so he will be eaten and not you. Do your systems have to be as secure as Pentagon computers with a myriad of controls? Not necessarily. Your system has to be more secure than your neighbor's, and hopefully you will avoid trouble. Here are some other techniques to deter intrusions:

- Deterring intrusions by snow flaking (no two snowflakes are the same, so it takes more time to analyze a

particular system in order to gain access, making them useless to be scanned with automatic tools). An example would be to move an SSH port from default TCP/22 to TCP/31234. Some determined hacker will find out pretty soon, but it will be an extra step for a script kiddie.
- Low hanging fruit is attacked most of the time by simply ignoring the pings to the host. This will deter some hackers (as there are many more systems that reply to ping), and it takes less time to detect those live IPs and scan them for vulnerabilities [7].

8. ANTIVIRUS SOFTWARE

The biggest fear for malware is the antivirus (AV) engine on the system. An antivirus can detect attack, but it might be too late already. AV is based on signatures in the files. Hackers bypass signature detection by encrypting their executables in unique ways. Every executable is encrypted in a unique way; AV engines are always losing ground because they are late arrivals in the detection game. If your AV engine fires, that means that the malware managed to slip by your IDS/IPS solution into the network and/or system.

9. HOMEGROWN INTRUSION DETECTION

In order to defeat a hacker, you have to think like a hacker. Let's take a look at what a robots.txt file looks like in a Web server. This file sits in the root of a Web page (for example, www.mywebpage.com/robots.txt); provides information to search engines of what should be cached and what should be skipped; shows how frequent crawling has to be done, and so on. Let's say you have sensitive files in a directory called "reports." This directory can be excluded from search engine crawlers and will not end up in search results. Other files and directories such as /private/, /adminpanel/, /phpmyadmin/ should be excluded from the search engine results. This technique looks great so far, but an experienced attacker will take a look at robots.txt file below and see what you don't want him to know!

Incorrect robots.txt implementation	Correct robots.txt implementation
Disallow: /adminpanel/ Disallow: /phpmyadmin/ Disallow: /backup/ Disallow: /uploads/	Move all sensitive directories into one directory called for example /private/ and disallow this directory: Disallow: /private/

A little customized robots.txt file would look like the following:

```
User-Agent: *

Disallow: /private/
Allow: /
User-Agent: hacker
Disallow: /please/go/to/an/easier/target/
```

It would give the attacker some clue that this is probably not the easiest target, and hopefully he or she will move to an easier one. Needless to say, it will not prevent a targeted attack [8]. So, if you have somebody trying to access a nonexisting directory "/please/go/to/an/easier/target/" on the server, it should give you a clue as to who is interested in your Web site.

10. FULL-PACKET CAPTURE DEVICES

Sometimes it is easier to detect intrusion on the wire by monitoring ingress and egress traffic. We have to be aware of out-of-band communications—for example, communication that comes to the corporate network via Global System for Mobile Communications (GSM) signals. These communications do not go through border routers of the company and thus cannot be inspected via this technology.

Packet capture appliance is a standalone device that performs packet capture. Although packet capture appliances may be deployed anywhere on a network, most are commonly placed at the entrances to the network (the Internet connections) and in front of critical equipment, such as servers containing sensitive information.

In general, packet capture appliances capture and record all network packets in full (both header and payload); however, some appliances may be configured to capture a subset of a network's traffic based on user-definable filters. For many applications, especially network forensics and incident response, it is critical to conduct full-packet capture, though filtered packet capture may be used at times for specific, limited information-gathering purposes.

Deployment

The network data that a packet capture appliance captures depends on where and how the appliance is installed on a network. There are two options for deploying packet capture appliances on a network. One option is to connect the appliance to the Switch Port Analyzer (SPAN) port (port mirroring) on a network switch or router. A second

option is to connect the appliance inline, so that network activity along a network route traverses the appliance (similar in configuration to a network tap, but the information is captured and stored by the packet capture appliance rather than passing on to another device). When connected via a SPAN port, the packet capture appliance may receive and record all Ethernet/IP activity for all of the ports of the switch or router.

When connected inline, the packet capture appliance captures only the network traffic traveling between two points—that is, traffic that passes through the cable to which the packet capture appliance is connected. There are also two general approaches to deploying packet capture appliances: centralized and decentralized.

Centralized

With a centralized approach, one high-capacity, high-speed packet capture appliance connects to the data-aggregation point. The advantage of a centralized approach is that with one appliance, you gain visibility over the network's entire traffic. This approach, however, creates a single point of failure that is a very attractive target for hackers; additionally, one would have to reengineer the network to bring traffic to the appliance, and this approach typically involves high costs.

Decentralized

With a decentralized approach, you place multiple appliances around the network, starting at the point(s) of entry and proceeding downstream to deeper network segments, such as workgroups. The advantages include: no network reconfiguration required; ease of deployment; multiple vantage points for incident response investigations; scalability; no single point of failure—if one fails, you have the others; if combined with electronic invisibility, this approach practically eliminates the danger of unauthorized access by hackers; and low cost. The disadvantage is the potential increased maintenance of multiple appliances.

In the past, packet capture appliances were sparingly deployed, oftenonly at the point of entry into a network. Packet capture appliances can now be deployed more effectively at various points around the network. When conducting incident response, the ability to see the network data flow from various vantage points is indispensable in reducing the time to resolution and narrowing down which parts of the network ultimately were affected. By placing packet capture appliances at the entry point and in front of each workgroup, following the path of a particular transmission deeper into the network would be simplified and much quicker. Additionally, the appliances placed in front of the workgroups would show intranet transmissions that the appliance located at the entry point would not be able to capture.

Capacity

Packet capture appliances come with capacities ranging from 500 Gigabytes (GB) to 32 Terabytes (TB) and more. Only a few organizations with extremely high network usage would have use for the upper ranges of capacities. Most organizations would be well served with capacities from 1 TB to 4 TB.

A good rule of thumb when choosing capacity is to allow 1 GB per day for heavy users, down to 1 GB per month for regular users. For a typical office of 20 people with average usage, 1 TB would be sufficient for about one to four years.

Features: Filtered versus Full-Packet Capture

Full-packet capture appliances capture and record all Ethernet/IP activity, while filtered packet capture appliances capture only a subset of traffic, based on a set of user-definable filters, such as IP address, MAC address, or protocol. Unless you use the packet capture appliance for a very specific purpose (narrow purpose covered by the filter parameters), it is generally best to use full-packet capture appliances or otherwise risk missing the vital data. Particularly, when using a packet capture for network forensics or cyber security purposes, it is paramount to capture everything because any packet not captured on the spot is a packet that is gone forever. It is impossible to know ahead of time the specific characteristics of the packets or transmissions needed, especially in the case of an advanced persistent threat (APT). APTs and other hacking techniques rely on the success of network administrators not knowing how they work and thus not having solutions in place to counteract them. Most APT attacks originate from Russia and China.

Encrypted versus Unencrypted Storage

Some packet capture appliances encrypt the captured data before saving it to disk, while others do not. Considering the breadth of information that travels on a network or Internet connection (and that at least a portion of it could be considered sensitive), encryption is a good idea for most situations as a measure to keep the captured data secure. Encryption is also a critical element of authentication of data for the purposes of data/network forensics.

Sustained Capture Speed versus Peak Capture Speed

The sustained captured speed is the rate at which a packet capture appliance can capture and record packets without interruption or error over a long period of time. This is different from the peak capture rate, which is the highest speed at which a packet capture appliance can capture and record packets. The peak capture speed can only be maintained for a short period of time, until the appliance's buffers fill up and it starts losing packets. Many packet capture appliances share the same peak capture speed of 1 Gigabytes per Second (Gbps), but actual sustained speeds vary significantly from model to model.

Permanent versus Overwritable Storage

A packet capture appliance with permanent storage is ideal for network forensics and permanent record-keeping purposes because the data captured cannot be overwritten, altered, or deleted. The only drawback of permanent storage is that eventually the appliance becomes full and requires replacement. Packet capture appliances with overwritable storage are easier to manage because once they reach capacity, they will start overwriting the oldest captured data with the new; however, network administrators run the risk of losing important capture data when it gets overwritten. In general, packet capture appliances with overwrite capabilities are useful for simple monitoring or testing purposes, for which a permanent record is not necessary. Permanent recording is a must for network forensics information gathering.

Data Security

Since packet capture appliances capture and store a large amount of data on network activity (including files, emails, and other communications), they could, in themselves, become attractive targets for hacking. A packet capture appliance deployed for any length of time should incorporate security features to protect the recorded network data from access by unauthorized parties. If deploying a packet capture appliance introduces too many additional concerns about security, the cost of securing it may outweigh the benefits. The best approach would be for the packet capture appliance to have built-in security features. These security features may include encryption, or methods to "hide" the appliance's presence on the network. For example, some packet capture appliances feature "electronic invisibility," that is, having a stealthy network profile by not requiring or using IP or MAC addresses.

Although on the face of it, connecting a packet capture appliance via a SPAN port appears to make it more secure, the packet capture appliance would ultimately still have to be connected to the network in order to allow management and data retrieval. Though not accessible via the SPAN link, the appliance would be accessible via the management link.

Despite the benefits, a packet capture appliance's remote access feature presents a security issue that could make the appliance vulnerable. Packet capture appliances that allow remote access should have a robust system in place to protect it against unauthorized access. One way to accomplish this is to incorporate a manual disable, such as a switch or toggle that allows the user to physically disable remote access. This simple solution is very effective, as it is doubtful that a hacker would have an easy time gaining physical access to the appliance in order to flip a switch.

A final consideration is physical security. All the network security features in the world are moot if someone is simply able to steal the packet capture appliance or make a copy of it and have ready access to the data stored on it. Encryption is one of the best ways to address this concern, though some packet capture appliances also feature tamperproof enclosures.

11. OUT-OF-BAND ATTACK VECTORS

What is the weakest link in any corporation? The answer is people. People fall into social engineering attacks; people bring "forgotten" Universal Serial Bus (USB) sticks and CDs from bathrooms/parking lots and plug them into their computers just out of curiosity. People bring their own devices from home and connect to corporate networks. BYOD or Bring Your Own Device is a big pain for IT administrators to manage. It also introduces additional risk because an employee's own devices might already be backdoored or infected, and by connecting these devices to the corporate network, employees are introducing a new risk. A social engineering attack with a lost CD is shown in Figure 3.7.

A Demyo plug is a full-blown Linux-based OS with many penetration testing tools preinstalled. It looks like an innocent power surge/split, but it has a Wireless Fidelity (Wi-Fi), Bluetooth, and GSM 3 g modem installed inside. Once connected to the power outlet, it immediately calls back home via GSM 3 g modem and establishes a connection. Once connected, penetration testers can use it as a jump box to do further penetration testing inside the local area network (LAN) of the corporation [9]. The Demyo plug is shown in Figure 3.8.

How do you prevent employees from bringing their "lost CDs" and "lost USB sticks" from parking lots and plugging them into their machines? A strong policy should be in place that disallows connecting nonapproved

FIGURE 3.7 A social engineering attack with a lost CD.

FIGURE 3.8 The Demyo plug.

hardware to workstations. It is not enough to just write a policy and consider the job done. Policy has to be enforced, and most importantly, policy has to be understood by employees. There is no way that rules can be followed if they are not understood. Another way to minimize risk is to provide security awareness training to employees, explaining typical social engineering attacks and how not to fall for them.

12. SECURITY AWARENESS TRAINING

Security awareness is the knowledge and attitude members of an organization possess regarding the protection of the physical and, especially, information assets of that organization. Many organizations require formal security awareness training for all workers when they join the organization and periodically thereafter (usually annually). Topics covered in security awareness training include the following:

- The nature of sensitive material and physical assets that they may come in contact with, such as trade secrets, privacy concerns, and government classified information
- Employee and contractor responsibilities in handling sensitive information, including the review of employee nondisclosure agreements
- Requirements for proper handling of sensitive material in physical form, which includes marking, transmission, storage, and destruction
- Proper methods for protecting sensitive information on computer systems, including password policy and use of the two-factor authentication
- Other computer security concerns, including malware, phishing, and social engineering
- Workplace security, including building access, wearing of security badges, reporting of incidents, and forbidden articles
- Consequences of failure to properly protect information, including the potential loss of employment, economic consequences to the firm, damage to individuals whose private records are divulged, and possible civil and criminal penalties

Being security aware means that you understand that there is the potential for some people to deliberately or accidentally steal, damage, or misuse the data that is stored within a company's computer system and throughout its organization. Therefore, it would be prudent to support the assets of the institution (information, physical, and personal) by trying to stop that from happening.

According to the European Network and Information Security Agency, "Awareness of the risks and available safeguards is the first line of defense for the security of information systems and networks." The focus of Security Awareness consultancy should be to achieve a long-term shift in the attitude of employees towards security, while promoting a cultural and behavioral change within an organization. Security policies should be viewed as key enablers for the organization, not as a series of rules restricting the efficient working of your business.

13. DATA CORRELATION

Data correlation is a technique used in information security to put all the pieces together and come up with some meaningful information. For example, if you see Linux system SSH connections coming in all day long, and after watching someone log in 200 times there is a successful login: What does it tell you? It should be a good starting point to suggest that a brute force attack is going on. All technologies help to find out intrusions; however, technologies do not find intrusions, people do. Appliances and sensors are typically good about finding bad events, but good events can combine into bad ones as well. Let's

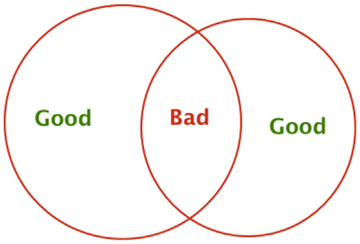

FIGURE 3.9 The combination of two good things can create one bad thing.

look at a simple scenario in which a human makes a determination about compromise:

Let's say there is a company with many employees who travel a lot around the globe. The company is doing a good job by implementing various control systems and logging systems; this company also uses Radio Frequency Identification (RFID) enabled cards for its employees in order to track who is coming and leaving its offices. All data is collected and pushed to the Security Information and Event Management (SIEM) engine to correlate events and logs. One morning two seemingly good events come into SIEM. The first event is user John's virtual private network (VPN) connection being established from overseas to the corporate office. The second event is user John's RFID badge being scanned at the entrance to the corporate office. Well, both events are pretty standard and are harmless when taken separately, but when combined, they reveal something weird. How can user John VPN in from overseas and get a physical entrance to the office at the same time? The answer is one of two: Either the VPN credentials have been compromised, or his employee card is being used by someone else to enter the office. Figure 3.9 shows how two good things can create one bad thing when combined.

14. SIEM

Security Information and Event Management (SIEM) solutions are a combination of the formerly disparate product categories of SIM (security information management) and SEM (security event manager). SIEM technology provides real-time analysis of security alerts generated by network hardware and applications. SIEM solutions come as software, appliances, or managed services, and they are also used to log security data and generate reports for compliance purposes.

The acronyms SEM, SIM, and SIEM have been used interchangeably, though there are differences in meaning and product capabilities. The segment of security management that deals with real-time monitoring, correlation of events, notifications, and console views is commonly known as Security Event Management (SEM). The second area provides long-term storage, analysis, and reporting of log data and is known as Security Information Management (SIM).

The term *Security Information Event Management* (SIEM) describes the product capabilities of gathering, analyzing, and presenting information from network and security devices; identity and access management applications; vulnerability management and policy compliance tools; operating system, database and application logs; and external threat data. A key focus is to monitor and help manage user and service privileges, directory services, and other system configuration changes, as well as providing log auditing and review and incident response. The following are a list of SIEM capabilities:

- *Data Aggregation*: SIEM/LM (log management) solutions aggregate data from many sources, including network, security, servers, databases, and applications, providing the ability to consolidate monitored data to help avoid missing crucial events.
- *Correlation*: Looks for common attributes and links events together into meaningful bundles. This technology provides the ability to perform a variety of correlation techniques to integrate different sources, in order to turn data into useful information.
- *Alerting*: The automated analysis of correlated events and production of alerts, to notify recipients of immediate issues.
- *Dashboards*: SIEM/LM tools take event data and turn it into informational charts to assist in seeing patterns or identifying activity that is not forming a standard pattern.
- *Compliance*: SIEM applications can be employed to automate the gathering of compliance data, producing reports that adapt to existing security, governance, and auditing processes.
- *Retention*: SIEM/SIM solutions employ long-term storage of historical data to facilitate the correlation of data over time and to provide the retention necessary for compliance requirements.

15. OTHER WEIRD STUFF ON THE SYSTEM

What are the other symptoms of possible system compromises? Following are some examples:

- Log files are missing completely. Why are there no log files? Script kiddies delete logs, whereas hackers modify them by taking out only their IP addresses, their commands, and manipulations with the system.
- Network interface is in a promiscuous mode: In computer networking, promiscuous mode is a mode for a wired network interface controller (NIC) or wireless network interface controller (WNIC) that causes the controller to pass all traffic it receives to the central

processing unit (CPU), rather than passing only the frames that the controller is intended to receive. This mode is normally used for packet sniffing that takes place on a router or on a computer connected to a hub (instead of a switch) or that is part of a wireless local area network (WLAN). The mode is also required for bridged networking for hardware virtualization.

In IEEE 802 networks such as Ethernet, token ring, IEEE 802.11, and FDDI, each frame includes a destination Media Access Control address (MAC address). In nonpromiscuous mode, when an NIC receives a frame, it normally drops it unless the frame is addressed to that NIC's MAC address or is a broadcast or multicast frame. In promiscuous mode, however, the card allows all frames through, thus allowing the computer to read frames intended for other machines or network devices.

Many operating systems require super user privileges to enable promiscuous mode. In a nonrouting node, promiscuous mode can generally only monitor traffic to and from other nodes within the same broadcast domain (for Ethernet and IEEE 802.11) or ring (for token ring or Fiber-Optic Data Distribution Interface (FDDI)). Computers attached to the same network hub satisfy this requirement, which is why network switches are used to combat malicious use of promiscuous mode. A router may monitor all traffic that it routes.

Promiscuous mode is often used to diagnose network connectivity issues. There are programs that make use of this feature to show the user all the data being transferred over the network. Some protocols like File Transfer Protocol (FTP), Telnet transfer data, passwords in clear text without encryption, and network scanners can see this data. Therefore, computer users are encouraged to stay away from insecure protocols like Telnet and use more secure ones such as secure shell (SSH).

16. DETECTION

As promiscuous mode can be used in a malicious way to sniff on a network, one might be interested in detecting network devices that are in a promiscuous mode. In promiscuous mode, some software might send responses to frames, even though they were addressed to another machine. However, experienced sniffers can prevent this (using carefully designed firewall settings).

An example of the preceding is sending a ping (Internet Control Message Protocol (ICMP) echo request) with the wrong Media Access Control (MAC) address, but the right IP address. If an adapter is operating in normal mode, it will drop this frame, and the IP stack never sees or responds to it. If the adapter is in promiscuous mode, the frame will be passed on, and the IP stack on the machine (to which a MAC address has no meaning) will respond, as it would to any other ping. The sniffer can prevent this by configuring his firewall to block ICMP traffic:

- Immutable files on the system that cannot be deleted can be found with the lsattr command. lsattr is a command-line program for listing the attributes on a Linux second extended file system. It is also a command to display attributes of devices on an Advanced Interactive eXecutive (AIX) operating system. Some malware puts a + i flag on its own executable, so you cannot delete it, even if you are a root.
- Mysterious open ports and services: All open ports and running services should be accounted for. For example, if there is a service running, but it's not clear what it does or why it is running, an investigation should be launched [10].

Finally, let's briefly look at the most common way to classify the detection of system intrusions (DSIs). Classification of the DSIs is to group them by information source. Some of the DSIs analyze network packets, captured from network backbones or LAN segments, in order to find attackers. Other DSIs analyze information sources generated by the operating system or application software for signs of intrusion.

17. NETWORK-BASED DETECTION OF SYSTEM INTRUSIONS (DSIS)

The majority of the commercial detection of system intrusions are network-based. These DSIs detect attacks by capturing and analyzing network packets. By listening on a network segment or switch, one network-based DSI can monitor the network traffic that is affecting multiple hosts connected to the network segment, thereby protecting those hosts.

Network-based DSIs often consist of a set of single-purpose sensors or hosts placed at various points in a network. These units monitor network traffic, performing local analysis of that traffic and reporting attacks to a central management console. As the sensors are limited to running the DSIs, they can be more easily secured against attack. Many of these sensors are designed to run in stealth mode, in order to make it more difficult for an attacker to determine their presence and location.

In addition, the following high-level checklist (see checklist: An Agenda for Action of the Advantages and Disadvantages of Network-Based DSIs) addresses the advantages and disadvantages of how the network-based DSIs monitor network traffic for particular network

An Agenda for Action of the Advantages and Disadvantages of Network-Based DSIs Activities

The following high-level checklist displays the advantages and disadvantages of how the network-based DSIs monitor network traffic for particular network segments (check all tasks completed):

Advantages

_____**1.** Install network-based DSIs so that they can monitor a large network.

_____**2.** Deploy network-based DSIs so that they have little impact on an existing network.

_____**3.** Make sure that the network-based DSIs listen in on a network wire without interfering with the normal operation of a network.

_____**4.** Retrofit a network to include network-based DSIs with minimal effort.

_____**5.** Make the network-based DSIs very secure against attack and invisible to attackers.

Disadvantages

_____**6.** Do your network-based DSIs have difficulty processing all packets in a large or busy network and, therefore, fail to recognize an attack launched during periods of high traffic?

_____**7.** Do your vendors implement DSIs completely in hardware, which is much faster?

_____**8.** Do your vendors analyze packets quickly, which forces them to both detect fewer attacks and also detect attacks with as little computing resource as possible, which can reduce detection effectiveness?

_____**9.** Is it true that many of the advantages of network-based DSIs don't apply to more modern switch-based networks?

_____**10.** Do switches subdivide networks into many small segments (usually one fast Ethernet wire per host) and provide dedicated links between hosts serviced by the same switch?

_____**11.** Do most switches that do not provide universal monitoring ports limit the monitoring range of a network-based DSIs sensor to a single host?

_____**12.** Do most switches that provide monitoring ports cause the single port to not mirror all traffic traversing the switch?

_____**13.** Is it true that network-based DSIs cannot analyze encrypted information?

_____**14.** Is the problem of not being able to analyze encrypted information increasing, as more organizations (and attackers) use virtual private networks?

_____**15.** Is it true that most network-based DSIs cannot tell whether or not an attack was successful, and that they can only discern that an attack was initiated?

_____**16.** Is it true that after a network-based DSIs detects an attack administrators must manually investigate each attacked host to determine whether it was indeed penetrated?

_____**17.** Do some network-based DSIs have problems dealing with network-based attacks that involve fragmenting packets?

_____**18.** Do malformed packets cause the DSIs to become unstable and crash?

segments or devices, and analyzes network, transport, and application protocols to identify suspicious activity. The network-based DSI components are similar to other types of DSI technologies, except for the sensors. A network-based DSI sensor monitors and analyzes network activity on one or more network segments. Sensors are available in two formats: appliance-based sensors, which are comprised of specialized hardware and software optimized for DSI sensor use; and software-only sensors, which can be installed onto hosts that meet certain specifications.

18. SUMMARY

As we outlined earlier, there are many ways to detect system intrusions and many ways to hide them. What is the proper way to analyze suspect systems then? The proper sequence is as follows:

1. Memory dump and analysis: Hackers are getting smart these days; they stay in the memory as long as possible. Why? Because they know forensics will be done on the HDD itself; but if they stay in memory, it requires a better skill to do memory analysis. Some companies just pull the plug from the power and network, and do HDD forensics analysis. This is wrong because as soon as you pull the power plug, half of the goodies are gone.
2. Selective HDD files analysis (we make the HDD image first, and work from the copy). Depending on the machine role on the network, doing a full-blown forensic analysis might be an overkill. In some situations, a partial forensic examination is enough.
3. A full HDD analysis is needed (we make the HDD image first and work from the copy).

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? One of the ways to monitor changes in the file system is to implement LoggedFS.
2. True or False? File integrity monitoring (FIM) is an internal control or process that performs the act of validating the integrity of the operating system and application software files using a verification method between the current file state and the known, good baseline.
3. True or False? A timestamp is a sequence of characters or encoded information identifying when a certain event occurred, usually giving date and time of day, sometimes accurate to a small fraction of a second.
4. True or False? A hidden file is normally visible when examining the contents of the directory in which it resides.
5. True or False? About 90 percent of all successful compromises are made via known flaws, so 0day attacks are common.

Multiple Choice

1. Values monitored for unexpected changes to files or configuration items include the following, except which one?
   - **A.** Credentials
   - **B.** Cannot be understood
   - **C.** Privileges and security settings
   - **D.** Content
   - **E.** Core attributes and size
2. What phase focuses on attack surface analysis?
   - **A.** Analyze
   - **B.** Test
   - **C.** Report
   - **D.** Mitigate
   - **E.** Cipher
3. Injection mechanisms include the following, except which one:
   - **A.** Use of vendor-supplied application extensions
   - **B.** Interception of messages
   - **C.** Buggers
   - **D.** Exploitation of security vulnerabilities
   - **E.** Function hooking or patching of commonly used APIs
4. What describes the product capabilities of gathering, analyzing, and presenting information from network and security devices; identity and access management applications; vulnerability management and policy compliance tools; operating system, database, and application logs; and external threat data?
   - **A.** Security Information Event Management
   - **B.** Security Information Management
   - **C.** Security Event Management
   - **D.** Security Management Information
   - **E.** Security Event Information
5. What is it called when SIEM/LM tools take event data and turn it into informational charts to assist in seeing patterns, or identifying activity that is not forming a standard pattern?
   - **A.** Compliance
   - **B.** Retention
   - **C.** Dashboards
   - **D.** Alerting
   - **E.** Correlation

EXERCISE

Problem

Which of the following attributes suggests that the packets below have been crafted?

00:03:21.680333 216.164.222.250.1186 > us.us.us.44.8080: S 2410044679:2410044679 (0) win 512
00:03:21.810732 216.164.222.250.1189 > us.us.us.50.8080: S 2410044679:2410044679 (0) win 512

Hands-On Projects

Project

What is the most likely reason for choosing to use HEAD requests instead of GET requests when scanning for the presence of vulnerable Web-based applications?

Case Projects

Problem

What is the LEAST effective indicator that the attacker's source address is not spoofed?

Optional Team Case Project

Problem

What is the most likely explanation for "arp info overwritten" messages on a BSD-based system?

Chapter 4

Preventing System Intrusions

Michael West
Senior Technical Writer, Truestone Maritime Operations

There's a war raging across the globe, and you're right in the middle of it. But while this war doesn't include gunfire and mass carnage, its effects can be thoroughly devastating nonetheless. This war is being waged in cyberspace by people bent on stealing the heart and soul of your business, your company's plans and secrets, or worse, your client names and their financial information.

So how bad is it? Just what are you up against?

Imagine this: You're in charge of security for an advanced movie screening. You've been hired and assigned the daunting task of keeping the advanced screening from being copied and turned into a bootleg version available overseas or on the Web. So how do you make sure that doesn't happen (how many times have we heard about this scenario or seen it in the movies)?

First, you might start by controlling access to the theater itself, allowing only the holders of very tightly controlled tickets into the screening. You post a couple of personnel at the door who carefully check every ticket against a list to verify the identity of both the ticket holder and their numbered ticket. Your goal is clear: restrict the viewers and, hopefully, reduce the possibility of someone entering with a counterfeit ticket. But what about the back stage door? While you're busy watching the front door, someone could simply sneak in the back. So, you secure that door and post a guard. But what about the ventilation system (the ventilation system is a favorite Hollywood scenario—remember Tom Cruise in *Mission Impossible*)? So, you secure that too. You also secure the projection room.

Did you think about a ticket holder coming into the theater with a digital recording device? Or a recording device surreptitiously planted just outside the projection room before anyone even entered. Or, worse, someone who rigged up a digital recording system that captures the movie from *inside* the projector and feeds it directly to their computer?

The point is this: No matter how diligent you are at securing your network, there are always people waiting just outside who are just as motivated to steal what you're trying to protect as you are trying to keep them from stealing it. You put up a wall; they use a back door. You secure the back door; they come in through a window. You secure the windows; they sneak in through the ventilation system. You secure the ventilation system; they simply bypass the physical security measures and go straight for your users, turning them into unwitting thieves. And so on and so on.

There's a very delicate balance between the need to keep your network secured and allowing user access. Users may be your company's lifeblood, but they are simultaneously your greatest and most necessary asset, and your weakest link.

It almost sounds like an impossible task, doesn't it? It's easy to see how it might seem that way when a casual Internet search reveals no shortage of sites selling hacking tools. In some cases, the hacking tools were written for—and marketed to—those not schooled in programming languages.

When I wrote this chapter three years ago, the cyber world was a very different place. Back then, crackers were simply stealing credit card numbers and financial data (for example, in January, hackers penetrated the customer database for online shoe store giant Zappos and stole names, email addresses, shipping addresses, phone numbers, and the last four digits of credit card numbers for over 24 million customers), siphoning corporate proprietary information (also known as industrial espionage), and defacing Web sites.

In today's world, crackers twice took control of an American satellite called Terra Eos, not just interrupting data flow, but taking full control of the satellite's guidance systems. They literally could have given the satellite commands to start a de-orbit burn.[1] And there's no shortage of some very simple and readily accessible software tools that allow crackers to sit nearby, say, in a coffee shop and wirelessly follow your Web browsing, steal your passwords, or even assume your identity.

Now, who do you think could pull off a feat like that? Most likely, it's not your neighbor's kid or the cyberpunk with just enough skill to randomly deface Web sites.

1. ABC News, November 16, 2011.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00004-0

Many experts believe this effort was well funded, most likely with government sponsorship. The Chinese military believes that attacking the communications links between ground stations and orbiting satellites is a legitimate strategy at the outset of any conflict. If that's the case, then a government-sponsored attack is a frightening prospect.

The moment you established an active Web presence, you put a target on your company's back. And like the hapless insect that lands in the spider's web, your company's size determines the size of the disturbance you create on the Web—and how quickly you're noticed by the bad guys. How attractive you are as prey is usually directly proportionate to what you have to offer a predator. If yours is an e-commerce site whose business thrives on credit card or other financial information or a company with valuable secrets to steal, your "juiciness" quotient goes up; you have more of value there to steal. And if your business is new and your Web presence is recent, the assumption could be made that perhaps you're not yet a seasoned veteran in the nuances of cyber warfare and, thus, are more vulnerable to an intrusion.

Unfortunately for you, many of those who seek to penetrate your network defenses are educated, highly motivated, and quite brilliant at developing faster and more efficient methods of quietly sneaking around your perimeter, checking for the smallest of openings. Most IT professionals know that an enterprise's firewall is relentlessly being probed for weaknesses and vulnerabilities by crackers from every corner of the globe. Anyone who follows news about software understands that seemingly every few months, word comes out about a new, exploitable opening in an operating system or application. It's widely understood that no one—not the most savvy network administrator, or the programmer who wrote the software—can possibly find and close all the holes in today's increasingly complex software.

Despite the increased sophistication of today's software applications, bugs and holes exist in those applications, as well as in operating systems, server processes (daemons), and client applications. System configurations can be easily exploited, especially if you don't change the default administrator's password, or if you simply accept default system settings, or unintentionally leave a gaping hole open by configuring the machine to run in a nonsecure mode. Even Transmission Control Protocol/Internet Protocol (TCP/IP), the foundation on which all Internet traffic operates, can be exploited, since the protocol was designed before the threat of hacking was really widespread. Therefore it contains design flaws that can allow, for example, a cracker to easily alter IP data.

Once the word gets out that a new and exploitable opening exists in an application (and word *will* get out), crackers around the world start scanning sites on the Internet searching for any and all sites that have that particular opening.

Making your job even harder is the fact that many of the openings into your network are caused by your employees. Casual surfing of online shopping sites, porn sites, and even banking sites can expose your network to all kinds of nasty bugs and malicious code, simply because an employee visited the site. The problem is that, to users, it might not seem like such a big deal. They either don't realize that they're leaving the network wide open to intrusion, or they don't care.

1. SO, WHAT IS AN INTRUSION?

A network intrusion is an unauthorized penetration of your enterprise's network, or an individual machine address in your assigned domain. Intrusions can be passive (in which the penetration is gained stealthily and without detection) or active (in which changes to network resources are effected). Intrusions can come from outside your network structure or inside (an employee, a customer, or business partner). Some intrusions are simply meant to let you know the intruder was there by defacing your Web site with various kinds of messages or crude images. Others are more malicious, seeking to extract critical information on either a one-time basis or as an ongoing parasitic relationship that continues to siphon off data until it's discovered. Some intruders implant carefully crafted code, such as Trojan-type malicious software (malware), designed to steal passwords, record keystrokes, or open an application's "back door."

Still worse, some high-end crackers can set up phony Web sites that exactly mimic your company's site, and surreptitiously redirect your unaware users away from your site to theirs (known as a "man in the browser attack"). Others will embed themselves into your network like a tick, quietly siphoning off data until found and rendered inert.

An attacker can get into your system physically (by gaining physical access to a restricted machine's hard drive and/or BIOS), externally (by attacking your Web servers or finding a way to bypass your firewall), or internally (your own users, customers, or partners).

2. SOBERING NUMBERS

So how often do these intrusions and data thefts occur? The estimates are staggering: In August of 2009, InfoTech Spotlight reported that "cybercrime costs organizations an average of $3.8 million per year,"[2] and there are thousands of new, fake phishing[3] Web sites set up

2. Bright Hub, "Cyber Crime Costs / Cyber Crime Losses," September 13, 2010.

3. Phishing is an attempt to steal user information (e.g., usernames, passwords, credit-card information, etc.) by disguising phony Web sites as legitimate ones the user may be accustomed to accessing.

online every day. The *APWG Phishing Activity Trends Report* for the first half of 2011 shows that even though unique phishing reports are down 35 percent (from an all-time high of 40,621 in August of 2009), data-stealing Trojan malware reached an all-time high in the first half of 2011 and comprised almost *half* of all detected malware. And from January to June of 2011, the number of new malware samples hit a whopping 11,777,775—an increase of 13 percent from the second half of 2010![4]

A March 2010 report by Security Management revealed that the most common Internet fraud complaints are from people whose identities have been compromised.[5] On two occasions, I myself have been the victim of a stolen credit-card number. In one case, a purchase was made at a jewelry store in Texas, and in the other, the purchases were made at a grocery store in the Philippines.

The Federal Bureau of Investigation (FBI) reports receiving over 330,000 identity theft reports, with losses estimated at over $560 million. And McAfee reports estimate business losses topped $1 trillion!Sadly, this number is likely to climb; 72 percent of newly detected malware are Trojans capable of stealing user information.

Not surprisingly, financial services are still the hardest hit and most frequently targeted sector, and account for almost half of all industry attacks. In the first half of 2011, new and more malevolent types of "Crimeware" (software specifically designed to steal customer information such as credit-card data, Social Security numbers, and customers' financial Web site credentials) appeared. Patrik Runald, senior manager of Security Research at Websense, has stated: "With cybercrime being an industry generating hundreds of millions of dollars for the bad guys, it's clear that this is a trend we will see for a long time."[6]

Unfortunately, the United States continues to host the highest number of infected phishing sites: Nearly 60 percent of all malware-infected URLs comes from the United States.

In today's cyber battlefield, attacks are specifically targeting one organization as a prelude to attacking and penetrating others. And if you're an enterprise's IT professional, you need to make a fundamental shift in mindset away from trying to build the most impressive defenses that money can buy to thinking seriously about defense and detection. The reality is, you have to assume you have been or soon will be compromised.

Even the big boys in cybersecurity aren't immune. In March of 2010, RSA was among hundreds of major companies compromised in a massive, coordinated cyber attack. The attackers penetrated RSA's formidable defenses and made off with information that RSA said could "reduce the effectiveness" of its widely used SecurID authentication system. In what the cyber security industry refers to as an "advanced persistent threat," the crackers used the information they stole from RSA to attack defense contractor Lockheed Martin.[7]

Whatever the goal of the intrusion—fun, greed, bragging rights, or data theft — the end result will be the same: Someone discovered and exploited a weakness in your network security, and until you discover that weakness—the intrusion entry point—it will continue to be an open door into your environment.

So, just who's out there looking to break into your network?

3. KNOW YOUR ENEMY: HACKERS VERSUS CRACKERS

An entire community of people—experts in programming and computer networking and those who thrive on solving complex problems—have been around since the earliest days of computing. The term *hacker* originated from the members of this culture, and they are quick to point out that it was hackers who built and make the Internet run, and hackers who created the Unix operating system. Hackers see themselves as members of a community that builds things and makes them work. And to those in their culture, the term *cracker* is a badge of honor.

Ask a traditional hacker about people who sneak into computer systems to steal data or cause havoc, and he'll most likely correct you by telling you those people aren't true hackers. (In the cracker community, the term for these types is *cracker*, and the two labels aren't synonymous.) So, to not offend traditional hackers, I'll use the term *crackers* and focus on them and their efforts.

From the lone-wolf cracker seeking peer recognition to the disgruntled former employee out for revenge or the deep pockets and seemingly unlimited resources of a hostile government bent on taking down wealthy capitalists, crackers are out there in force, looking to find the chink in your system's defensive armor.

The crackers' specialty—or in some cases, their mission in life—is to seek out and exploit the vulnerabilities of an individual computer or network for their own purposes. Crackers' intentions are normally malicious and/or criminal in nature. They have, at their disposal, a vast library of information designed to help them hone their tactics, skills, and knowledge, and they can tap into the almost unlimited experience of other crackers through a

7. CNNMoney, February 28, 2012.

community of like-minded individuals sharing information across underground networks.

They usually begin this life learning the most basic of skills: software programming. The ability to write code that can make a computer do what they want is seductive in and of itself. As they learn more and more about programming, they also expand their knowledge of operating systems and, as a natural course of progression, operating systems' weaknesses. They also quickly learn that, to expand the scope and type of their illicit handiwork, they need to learn HTML—the code that allows them to create phony Web pages that lure unsuspecting users into revealing important financial or personal data.

There are vast underground organizations to which these new crackers can turn for information. They hold meetings, write papers, and develop tools that they pass along to each other. Each new acquaintance they meet fortifies their skill set and gives them the training to branch out to more and more sophisticated techniques. Once they gain a certain level of proficiency, they begin their trade in earnest.

They start off simply by researching potential target firms on the Internet (an invaluable source for all kinds of corporate network related information). Once a target has been identified, they might quietly tiptoe around, probing for old forgotten back doors and operating system vulnerabilities. As starting points for launching an attack, they can simply and innocuously run basic DNS queries that can provide IP addresses (or ranges of IP addresses). They might sit back and listen to inbound and/or outbound traffic, record IP addresses, and test for weaknesses by pinging various devices or users.

To breach your network, a cracker starts by creating a chain of exploited systems in which each successful takeover sets the stage for the next. The easiest systems to exploit are those in our homes: Most home users do little to secure their systems from outside intrusions. And a good cracker can implant malware so deeply in a home computer that the owner never knows it's there. Then, when they're asleep or away, the malware takes control of the home computer and starts sending out newly mutated versions to another compromised system. In this way, there are so many compromised systems between them and the intrusion that it sends investigators down long, twisted paths that can include dozens, if not hundreds, of unwittingly compromised systems. Once your network is breached, they can surreptitiously implant password cracking or recording applications, keystroke recorders, or other malware designed to keep their unauthorized connection alive—and profitable. From there, they sit back and siphon off whatever they deem most valuable.

The cracker wants to act like a cyber-ninja, sneaking up to and penetrating your network without leaving any trace of the incursion. Some more seasoned crackers can put multiple layers of machines, many hijacked, between them and your network to hide their activity. Like standing in a room full of mirrors, the attack appears to be coming from so many locations you can't pick out the real from the ghost. And before you realize what they've done, they've up and disappeared like smoke in the wind.

4. MOTIVES

Though the goal is the same—to penetrate your network defenses—crackers' motives are often different. In some cases, a network intrusion could be done from the inside by a disgruntled employee looking to hurt the organization or steal company secrets for profit.

There are large groups of crackers working diligently to steal credit-card information that they then turn around and make available for sale. They want a quick grab and dash—take what they want and leave. Their cousins are the network parasites—those who quietly breach your network, then sit there siphoning off data.

A new and very disturbing trend is the discovery that certain governments have been funding digital attacks on network resources of both federal and corporate systems. Various agencies from the U.S. Department of Defense to the governments of New Zealand, France, and Germany have reported attacks originating from unidentified Chinese hacking groups. It should be noted that the Chinese government denies any involvement, and there is no evidence that it is or was involved.

5. THE CRACKERS' TOOLS OF THE TRADE

Over the years, the tools available to crackers have become increasingly more sophisticated. How sophisticated?

Most security software products available today have three basic methods of spotting malicious software. First, it scans all incoming data traffic for traces of known malware (pulling malware characteristics from a source database). Then, it looks for any kind of suspicious activity (e.g., vulnerable processes unexpectedly activating or running too long, unusual activity during normally dormant periods, etc.). And finally, the security software checks for indications of information leaving from abnormal paths or processes.

Recently, however, a relatively new and extremely malicious malware program called Zeus has appeared. Designed specifically to steal financial information, Zeus can defeat the above methods by not only sitting discreetly and quietly—not drawing attention to itselfbut also by changing its appearance tens of thousands of times per day. But its most insidious characteristic is that it siphons data off from an infected system using your

browser. Called a "man in the browser attack," Zeus implants itself in your browser, settling in between you and a legitimate Web site (say, the site for the financial institution that manages your IRA), and very capably altering what you see to the point at which you really can't tell the difference. Not knowing the difference, you confidently enter your most important financial details, which Zeus siphons off and sends to someone else. New Zeus updates come out regularly, and, once released, it can take weeks for its new characteristics to become known by security software companies.

Our "Unsecured" Wireless World

Do you think much about the time you spend using a coffee shop's free Wi-Fi signal to surf, check your email, or update your Facebook page? Probably not. But today, the person sitting next to you quietly sipping her coffee and working away on her laptop can now sit back and watch what Web sites you've visited, then assume your identity and log on to the sites you visited. How? A free program called Firesheep can grab from your Web browser the cookies[8] for each site you visit. That cookie contains identifying information about your computer, and site settings for each site you visit plus your customized private information for that site. Once Firesheep grabs that cookie, a malicious user can use it to log on to sites as you, and can, in some cases, gain full access to your account.

You may be asking yourself "So what does this have to do with my network?" If the unsuspecting user is wirelessly completing a sales transaction or bank transfer when software like Firesheep snatches the browser cookie, the cracker can log back into your site as the compromised user and drain your account.

In years past, only the most experienced and savvy crackers with expensive tools and plenty of time could do much damage to secured networks. But like a professional thief with custom-made lock picks, crackers today can obtain a frightening array of tools to covertly test your network for weak spots. Their tools range from simple password-stealing malware and keystroke recorders (loggers) to methods of implanting sophisticated parasitic software strings that copy data streams coming in from customers who want to perform an e-commerce transaction with your company. Some of the more widely used tools include these:

- *Wireless sniffers.* Not only can these devices locate wireless signals within a certain range, they can siphon off the data being transmitted over the signals. With the rise in popularity and use of remote wireless devices, this practice is increasingly responsible for the loss of critical data and represents a significant headache for IT departments.
- *Packet sniffers.* Once implanted in a network data stream, these tools passively analyze data packets moving into and out of a network interface, and utilities capture data packets passing through a network interface.
- *Port scanners.* A good analogy for these utilities is a thief casing a neighborhood, looking for an open or unlocked door. These utilities send out successive, sequential connection requests to a target system's ports to see which one responds or is open to the request. Some port scanners allow the cracker to slow the rate of port scanning—sending connection requests over a longer period of time—so the intrusion attempt is less likely to be noticed. The usual targets of these devices are old, forgotten "back doors," or ports inadvertently left unguarded after network modifications.
- *Port knocking.* Sometimes network administrators create a secret backdoor method of getting through firewall-protected ports—a secret knock that enables them to quickly access the network. Port-knocking tools find these unprotected entries and implant a Trojan horse that listens to network traffic for evidence of that secret knock.
- *Keystroke loggers.* These are spyware utilities planted on vulnerable systems that record a user's keystrokes. Obviously, when someone can sit back and record every keystroke a user makes, it doesn't take long to obtain things like usernames, passwords, and ID numbers.
- *Remote administration tools.* Programs embedded on an unsuspecting user's system that allow the cracker to take control of that system.
- *Network scanners.* Explore networks to see the number and kind of host systems on a network, the services available, the host's operating system, and the type of packet filtering or firewalls being used.
- *Password crackers.* These sniff networks for data streams associated with passwords, then employ a brute-force method of peeling away any encryption layers protecting those passwords.

6. BOTS

Three years ago, bots were an emerging threat. Now , organized cyber criminals have begun to create and sell kits on the open market that inexperienced nonprogramming crackers can use to create their own botnets. It offers a wide variety of easy to use (or pre-programmed) modules that specifically target the most lucrative

8. Cookies are bits of software code sent to your browser by Web sites. They can be used for authentication, session identification, preferences, shopping cart contents, and so on.

technologies. It includes a management console that can control every infected system and interrogate bot-infected machines. If desired, Zeus kit modules are available that can allow the user to create viruses that mutate every time they're implanted in a new host system.

So what are bots? Bots, also known as an Internet bots, Web robots, or WWW robots, are small software applications running automated tasks over the Internet. Usually, they run simple tasks that a human would otherwise have to perform, but at a much faster rate. When used maliciously, they are a virus, surreptitiously implanted in large numbers of unprotected computers (usually those found in homes), hijacking them (without the owners' knowledge) and turning them into slaves to do the cracker's bidding. These compromised computers, known as *bots*, are linked in vast and usually untraceable networks called *botnets.* Botnets are designed to operate in such a way that instructions come from a central PC and are rapidly shared among other botted computers in the network. Newer botnets are now using a "peer-to-peer" method that, because they lack a central identifiable point of control, makes it difficult if not impossible for law enforcement agencies to pinpoint. And because they often cross international boundaries into countries without the means (or will) to investigate and shut them down, they can grow with alarming speed. They can be so lucrative that they've now become the cracker's tool of choice.

There are all kinds of bots; there are bots that harvest email addresses (spambots), viruses and worms, filename modifiers, bots to buy up large numbers of concert seats, and bots that work together in botnets, or coordinated attacks on networked computers.

Botnets exist largely because of the number of users who fail to observe basic principles of computer security—installed and/or up-to-date antivirus software, regular scans for suspicious code, and so on—and thereby become unwitting accomplices. Once taken over and "botted," their machines are turned into channels through which large volumes of unwanted spam or malicious code can be quickly distributed. Current estimates are that, of the 800 million computers on the Internet, up to 40 percent are bots controlled by cyber thieves who are using them to spread new viruses, send out unwanted spam email, overwhelm Web sites in denial-of-service (DoS) attacks, or siphon off sensitive user data from banking or shopping Web sites that look and act like legitimate sites with which customers have previously done business.

Bot controllers, also called *herders*, can also make money by leasing their networks to others who need a large and untraceable means of sending out massive amounts of advertisements but don't have the financial or technical resources to create their own networks. Making matters worse is the fact that botnet technology is available on the Internet for less than $100, which makes it relatively easy to get started in what can be a very lucrative business.

7. SYMPTOMS OF INTRUSIONS

As stated earlier, merely being on the Web puts a target on your back. It's only a matter of time before you experience your first attack. It could be something as innocent looking as several failed login attempts or as obvious as an attacker having defaced your Web site or crippled your network. It's important that you go into this knowing you're vulnerable.

Crackers are going to first look for known weaknesses in the operating system (OS) or any applications you are using. Next, they would start probing, looking for holes, open ports, or forgotten back doors—faults in your security posture that can quickly or easily be exploited.

Arguably one of the most common symptoms of an intrusion—either attempted or successful—is repeated signs that someone is trying to take advantage of your organization's own security systems, and the tools you use to keep watch for suspicious network activity may actually be used against you quite effectively. Tools such as network security and file integrity scanners, which can be invaluable in helping you conduct ongoing assessments of your network's vulnerability, are also available and can be used by crackers looking for a way in.

Large numbers of unsuccessful login attempts are also a good indicator that your system has been targeted. The best penetration-testing tools can be configured with attempt thresholds that, when exceeded, will trigger an alert. They can passively distinguish between legitimate and suspicious activity of a repetitive nature, monitor the time intervals between activities (alerting when the number exceeds the threshold you set), and build a database of signatures seen multiple times over a given period.

The "human element" (your users) is a constant factor in your network operations. Users will frequently enter a mistyped response but usually correct the error on the next try. However, a sequence of mistyped commands or incorrect login responses (with attempts to recover or reuse them) can be a signs of brute-force intrusion attempts.

Packet inconsistencies—direction (inbound or outbound), originating address or location, and session characteristics (ingoing sessions vs. outgoing sessions)—can also be good indicators of an attack. If a packet has an unusual source or has been addressed to an abnormal port—say, an inconsistent service request—it could be a sign of random system scanning. Packets coming from the outside that have local network addresses that request services on the inside can be a sign that IP spoofing is being attempted.

Sometimes odd or unexpected system behavior is itself a sign. Though this is sometimes difficult to track, you should be aware of activity such as changes to system clocks, servers going down or server processes inexplicably stopping (with system restart attempts), system resource issues (such as unusually high CPU activity or overflows in file systems), audit logs behaving in strange ways (decreasing in size without administrator intervention), or unexpected user access to resources. You should investigate any and all unusual activity at regular times on given days, heavy system use (possible denial of service (DoS) attack) or CPU use (brute-force password-cracking attempts).

8. WHAT CAN YOU DO?

It goes without saying that the most secure network—the one that has the least chance of being compromised—is the one that has no direct connection to the outside world. But that's hardly a practical solution, since the whole reason you have a Web presence is to do business. And in the game of Internet commerce, your biggest concern isn't the sheep coming in but the wolves dressed like sheep coming in with them. So, how do you strike an acceptable balance between keeping your network intrusion free and keeping it accessible at the same time?

As your company's network administrator, you walk a fine line between network security and user needs. You have to have a good defensive posture that still allows for access. Users and customers can be both the lifeblood of your business and its greatest potential source of infection. Furthermore, if your business thrives on allowing users access, you have no choice but to let them in. It seems like a monumentally difficult task at best.

Like a castle, imposing but stationary, every defensive measure you put up will eventually be compromised by the legions of very motivated thieves looking to get in. It's a game of move/countermove: You adjust, they adapt. So you have to start with defenses that can quickly and effectively adapt and change as the outside threats adapt.

First and foremost, you need to make sure that your perimeter defenses are as strong as they can be, and that means keeping up with the rapidly evolving threats around you. The days of relying solely on a firewall that simply does firewall functions are gone; today's crackers have figured out how to bypass the firewall by exploiting weaknesses in applications themselves. Simply being reactive to hits and intrusions isn't a very good option either; that's like standing there waiting for someone to hit you before deciding what to do rather than seeing the oncoming punch and moving out of its way or blocking it. You need to be flexible in your approach to the newest technologies, constantly auditing your defenses to ensure that your network's defensive armor can meet the latest threat. You have to have a very dynamic and effective policy of constantly monitoring for suspicious activities that, when discovered, can be quickly dealt with so that someone doesn't slip something past without your noticing it. Once that happens, it's too late.

Next, and this is also a crucial ingredient for network administrators: You have to educate your users. No matter how good a job you've done at tightening up your network security processes and systems, you still have to deal with the weakest link in your armor—your users. It doesn't do any good to have bulletproof processes in place if they're so difficult to manage that users work around them to avoid the difficulty, or if they're so loosely configured that a casually surfing user who visits an infected site will pass that infection along to your network. The degree of difficulty in securing your network increases dramatically as the number of users goes up.

User education becomes particularly important where mobile computing is concerned. Losing a device, using it in a place (or manner) in which prying eyes can see passwords or data, awareness of hacking tools specifically designed to sniff wireless signals for data, and logging on to unsecured networks are all potential problem areas with which users need to be familiar.

A relatively new tool is the intrusion detection system, or IDS. IDSs merge their deep packet scanning with a firewall's blocking can filtering capabilities. A good IDS and not only detect intrusion attempts, but also stop the attack before it does any damage.

One type of IDS, known as an inline IDS, can sit between your network's outside interface and your most critical systems. They essentially inspect every data packet headed for those critical systems, sniffing and "tasting" them, then scrubbing out the ones that have suspicious characteristics.

Another type of IDS is based on an application firewall scheme. These types of IDSs sit on all protected servers and are configured to protect specific applications. They are designed to "learn" every aspect of an application—how it interacts with users and the Internet, how the application's features play with each other, and what "customizable" features the application has that may require more detailed configuration—then create a rule for dealing with those aspects. This last point reveals a drawback of application-based IDSs: In order for them to protect all aspects of the application, it has to "know" every aspect of the application. The only way you can configure the IDS to protect every one of the application's functions is to let it "learn" the functions by exercising them. It can't develop a protection rule for a feature with which it's unfamiliar. So thorough testing is needed, or the IDS may miss a particular vulnerability. And if you update the protected application, you'll need

to exercise its features again to ensure the IDS knows what it's supposed to protect.

You can also set up a decoy—sort of the "sacrificial lamb"—as bait. Also known as "honey pots," these userless networks are specifically set up to draw in an attacker and gain valuable data on the methods, tools, and any new malware they might be using.

Know Today's Network Needs

The traditional approach to network security engineering has been to try to erect preventative measures—firewalls—to protect the infrastructure from intrusion. The firewall acts like a filter, catching anything that seems suspicious and keeping everything behind it as sterile as possible. However, though firewalls are good, they typically don't do much in the way of identifying compromised applications that use network resources. And with the speed of evolution seen in the area of penetration tools, an approach designed simply to prevent attacks will be less and less effective.

Today's computing environment is no longer confined to the office, as it used to be. Though there are still fixed systems inside the firewall, ever more sophisticated remote and mobile devices are making their way into the workforce. This influx of mobile computing has expanded the traditional boundaries of the network to farther and farther reaches and requires a different way of thinking about network security requirements.

Your network's endpoint or perimeter is mutating—expanding beyond its historical boundaries. Until recently, that endpoint was the user, either a desktop system or laptop, and it was relatively easy to secure those devices. To use a metaphor: The difference between endpoints of early network design and those of today is like the difference between the battles of World War II and the current war on terror. In the World War II battles there were very clearly defined "front lines"—one side controlled by the Allied powers, the other by the Axis. Today, the war on terror has no such front lines and is fought in multiple areas with different techniques and strategies that are customized for each combat theater.

With today's explosion of remote users and mobile computing, your network's endpoint is no longer as clearly defined as it once was, and it is evolving at a very rapid pace. For this reason, your network's physical perimeter can no longer be seen as your best "last line of defense," even though having a robust perimeter security system is still a critical part of your overall security policy.

Any policy you develop should be organized in such a way as to take advantage of the strength of your unified threat management (UTM) system. Firewalls, antivirus, and intrusion detection systems (IDSs), for example, work by trying to block all currently known threats—the "blacklist" approach. But the threats evolve more quickly than the UTM systems can, so it almost always ends up being an "after the fact" game of catch-up. Perhaps a better, and more easily managed, policy is to specifically state which devices are allowed access and which applications are allowed to run in your network's applications. This "whitelist" approach helps reduce the amount of time and energy needed to keep up with the rapidly evolving pace of threat sophistication, because you're specifying what gets in versus what you have to keep out.

Any UTM system you employ should provide the means of doing two things: specify which applications and devices are allowed and offer a policy-based approach to managing those applications and devices. It should allow you to secure your critical resources against unauthorized data extraction (or data leakage), offer protection from the most persistent threats (viruses, malware, and spyware), and evolve with the ever-changing spectrum of devices and applications designed to penetrate your outer defenses.

So, what's the best strategy for integrating these new remote endpoints? First, you have to realize that these new remote, mobile technologies are becoming increasingly ubiquitous and aren't going away anytime soon. In fact, they most likely represent the future of computing. As these devices gain in sophistication and function, they are unchaining end users from their desks and, for some businesses, are indispensable tools. iPhones, Blackberries, Palm Treos, and other smart phones and devices now have the capability to interface with corporate email systems, access networks, run enterprise-level applications, and do full-featured remote computing. As such, they also now carry an increased risk for network administrators due to loss or theft (especially if the device is unprotected by a robust authentication method) and unauthorized interception of their wireless signals from which data can be siphoned off.

To cope with the inherent risks, you engage an effective security policy for dealing with these devices: Under what conditions can they be used, how many of your users need to employ them, what levels and types of access will they have, and how will they be authenticated?

Solutions are available for adding strong authentication to users seeking access via wireless LANs. Tokens, either of the hardware or software variety, are used to identify the user to an authentication server for verification of their credentials. For example, SafeNet's SafeWord can handle incoming access requests from a wireless access point and, if the user is authenticated, pass them into the network.

Key among the steps you take to secure your network while allowing mobile computing is to fully educate the users of such technology. They need to understand, in no

uncertain terms, the risks to your network (and ultimately to the company in general) represented by their mobile devices, and they also need to be aware that their mindfulness of both the device's physical and electronic security is an absolute necessity.

Network Security Best Practices

So, how do you either clean and tighten up your existing network, or design a new one that can stand up to the inevitable onslaught of attacks? Let's look at some basics. Consider the diagram shown in Figure 4.1.

Figure 4.1 shows what could be a typical network layout. Users outside the DMZ approach the network via a secure (HTTPS) Web or VPN connection. They are authenticated by the perimeter firewall and handed off to either a Web server or a virtual private network (VPN) gateway. If allowed to pass, they can then access resources inside the network.

If you're the administrator of an organization that has only, say, a couple dozen users with whom to contend, your task (and the illustration layout) will be relatively easy to manage. But if you have to manage several hundred (or several thousand) users, the complexity of your task increases by an order of magnitude. That makes a good security policy an absolute necessity.

9. SECURITY POLICIES

Like the tedious prep work before painting a room, organizations need a good, detailed, and well-written security policy. Not something that should be rushed through "just to get it done," your security policy should be well thought out; in other words, the "devil is in the details." Your security policy is designed to get everyone involved with your network "thinking along the same lines."

The policy is almost always a work in progress. It must evolve with technology, especially those technologies aimed at surreptitiously getting into your system. The threats will continue to evolve, as will the systems designed to hold them at bay.

A good security policy isn't always a single document; rather, it is a conglomeration of policies that address specific areas, such as computer and network use, forms of authentication, email policies, remote/mobile technology use, and Web surfing policies. It should be written in such a way that, while comprehensive, it can be easily understood by those it affects. Along those lines, your policy doesn't have to be overly complex. If you hand new employees something that resembles *War and Peace* in size and tell them they're responsible for knowing its content, you can expect to have continued problems maintaining good network security awareness. Keep it simple.

First, you need to draft some policies that define your network and its basic architecture. A good place to start is by asking the following questions:

- What kinds of resources need to be protected (user financial or medical data, credit-card information, etc.)?
- How many users will be accessing the network on the inside (employees, contractors, etc.)?

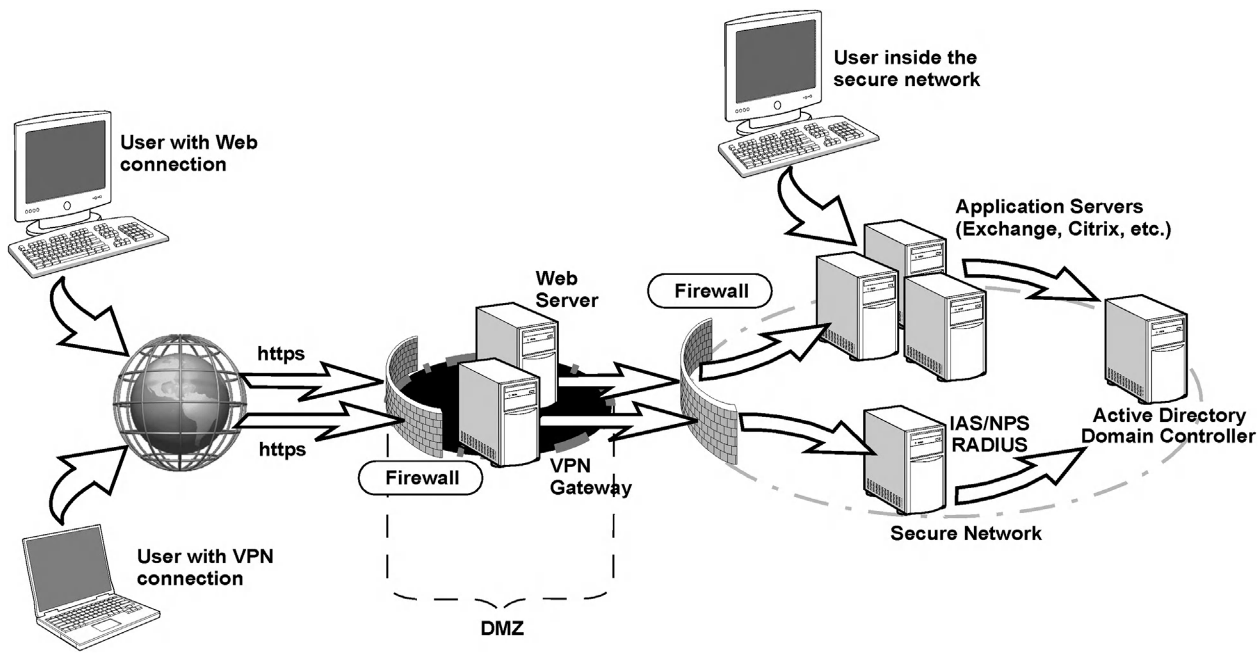

FIGURE 4.1 Network diagram.

- Will there need to be access only at certain times or on a 24/7 basis (and across multiple time zones and/or internationally)?
- What kind of budget do I have?
- Will remote users be accessing the network, and if so, how many?
- Will there be remote sites in geographically distant locations (requiring a failsafe mechanism, such as replication, to keep data synched across the network)?

Next, you should spell out responsibilities for security requirements, communicate your expectations to your users (one of the weakest links in any security policy), and lay out the role(s) for your network administrator. It should list policies for activities such as Web surfing, downloading, local and remote access, and types of authentication. You should address issues such as adding users, assigning privileges, dealing with lost tokens or compromised passwords, and under what circumstances you will remove users from the access database.

You should establish a security team (sometimes referred to as a "tiger team") whose responsibility it will be to create security policies that are practical, workable, and sustainable. They should come up with the best plan for implementing these policies in a way that addresses both network resource protection and user friendliness. They should develop plans for responding to threats as well as schedules for updating equipment and software. And there should be a very clear policy for handling changes to overall network security—the types of connections through your firewall that will and will not be allowed. This is especially important because you don't want an unauthorized user gaining access, reaching into your network, and simply taking files or data.

10. RISK ANALYSIS

You should have some kind of risk analysis done to determine, as near as possible, the risks you face with the kind of operations you conduct (e-commerce, classified/proprietary information handling, partner access, or the like). Depending on the determined risk, you might need to rethink your original network design. Although a simple extranet/intranet setup with mid-level firewall protection might be okay for a small business that doesn't have much to steal, that obviously won't work for a company that deals with user financial data or proprietary/classified information. In that case, what might be needed is a tiered system in which you have a "corporate side" (on which things such as email, intranet access, and regular Internet access are handled) and a separate, secure network not connected to the Internet or corporate side. These networks can only be accessed by a user on a physical machine, and data can only be moved to them by "sneaker-net" physical media (scanned for viruses before opening). These networks can be used for data systems such as test or lab machines (on which, for example, new software builds are done and must be more tightly controlled, to prevent inadvertent corruption of the corporate side), or networks on which the storage or processing of proprietary, business-critical, or classified information are handled. In Department of Defense parlance, these are sometimes referred to as *red nets* or *black nets.*

Vulnerability Testing

Your security policy should include regular vulnerability testing. Some very good vulnerability testing tools, such as WebInspect, Acunetix, GFI LANguard, Nessus, HFNetChk, and Tripwire, allow you to conduct your own security testing. Furthermore, there are third-party companies with the most advanced suite of testing tools available that can be contracted to scan your network for open and/or accessible ports, weaknesses in firewalls, and Web site vulnerability.

Audits

You should also factor in regular, detailed audits of all activities, with emphasis on those that seem to be near or outside established norms. For example, audits that reveal high rates of data exchanges after normal business hours, when that kind of traffic would not normally be expected, is something that should be investigated. Perhaps, after checking, you'll find that it's nothing more than an employee downloading music or video files. But the point is that your audit system saw the increase in traffic and determined it to be a simple Internet use policy violation rather than someone siphoning off more critical data.

There should be clearly established rules for dealing with security, use, and/or policy violations as well as attempted or actual intrusions. Trying to figure out what to do after the intrusion is too late. And if an intrusion does occur, there should be a clear-cut system for determining the extent of damage; isolation of the exploited application, port, or machine; and a rapid response to closing the hole against further incursions.

Recovery

Your plan should also address the issue of recovery after an attack has occurred. You need to address issues such as how the network will be reconfigured to close off the exploited opening. This might take some time, since the entry point might not be immediately discernible. There has to be an estimate of damage—what was taken or compromised, was malicious code implanted somewhere, and, if so, how to most efficiently extract it and clean the

affected system. In the case of a virus in a company's email system, the ability to send and receive email could be halted for days while infected systems are rebuilt. And there will have to be discussions about how to reconstruct the network if the attack decimated files and systems.

This will most likely involve more than simply reinstalling machines from archived backups. Because the compromise will most likely affect normal business operations, the need to expedite the recovery will hamper efforts to fully analyze just what happened.

This is the main reason for preemptively writing a disaster recovery plan and making sure that all departments are represented in its drafting. However, like the network security policy itself, the disaster recovery plan will also be a work in progress that should be reviewed regularly to ensure that it meets the current needs. Things such as new threat notifications, software patches and updates, vulnerability assessments, new application rollouts, and employee turnover all have to be addressed.

11. TOOLS OF YOUR TRADE

Although the tools available to people seeking unauthorized entry into your domain are impressive, you also have a wide variety of tools to help keep them out. Before implementing a network security strategy, however, you must be acutely aware of the specific needs of those who will be using your resources.

Simple antispyware and antispam tools aren't enough. In today's rapidly changing software environment, strong security requires penetration shielding, threat signature recognition, autonomous reaction to identified threats, and the ability to upgrade your tools as the need arises.

The following section describes some of the more common tools you should consider adding to your arsenal.

Intrusion Detection Systems (IDSs)

As discussed earlier in the chapter, it's no longer good enough to have solid defenses. You also need to know when you've been penetrated—and the sooner, the better. Statistics paint a dismal picture. According to Verizon's threat report, less than 5 percent of cybersecurity breaches are detected within hours of the assault, and 80 percent weren't found for weeks, or months.[9] Bret Hartman, RSA's chief technology officer said, in a recent interview, that there's a new "shift in the level of paranoia to assume that you're always in a state of partial compromise."

A good IDS detects unauthorized intrusions using one of three types of models: anomaly-based, signature-based, and hybrid detection.

9. CNNMoney Tech, February 28, 2012.

- Anomaly-based systems learn what's "normal" for a given network environment, so that they can quickly detect the "abnormal."
- Signature-based systems look for slight variations, or signatures, of suspicious network activity;
- Hybrid detection systems are currently in development which compensate for weaknesses of both anomaly and signature-based systems by combining the best of both.

Firewalls

Your first line of defense should be a good firewall, or better yet, a system that effectively incorporates several security features in one. Secure Firewall (formerly Sidewinder) from Secure Computing is one of the strongest and most secure firewall products available, and as of this writing it has never been successfully hacked. It is trusted and used by government and defense agencies. Secure Firewall combines the five most necessary security systems—firewall, antivirus/spyware/spam, VPN, application filtering, and intrusion prevention/detection systems—into a single appliance.

Intrusion Prevention Systems

A good *intrusion prevention system* (IPS) is a vast improvement over a basic firewall in that it can, among other things, be configured with policies that allow it to make autonomous decisions as to how to deal with application-level threats as well as simple IP address or port-level attacks.

IPS products respond directly to incoming threats in a variety of ways, from automatically dropping (extracting) suspicious packets (while still allowing legitimate ones to pass) to, in some cases, placing an intruder into a "quarantine" file. IPS, like an application layer firewall, can be considered another form of access control in that it can make pass/fail decisions on application content.

For an IPS to be effective, it must also be very good at discriminating between a real threat signature and one that looks like but isn't one (false positive). Once a signature interpreted to be an intrusion is detected, the system must quickly notify the administrator so that the appropriate evasive action can be taken. The following are types of IPS.

- *Network-based.* Network-based IPSs create a series of choke points in the enterprise that detect suspected intrusion attempt activity. Placed inline at their needed locations, they invisibly monitor network traffic for known attack signatures that they then block.
- *Host-based.* These systems don't reside on the network per se but rather on servers and individual

machines. They quietly monitor activities and requests from applications, weeding out actions deemed prohibited in nature. These systems are often very good at identifying post-decryption entry attempts.

- *Content-based.* These IPSs scan network packets, looking for signatures of content that is unknown or unrecognized or that has been explicitly labeled threatening in nature.
- *Rate-based.* These IPSs look for activity that falls outside the range of normal levels, such as activity that seems to be related to password cracking and brute-force penetration attempts, for example.

When searching for a good IPS, look for one that provides, at minimum:

- Robust protection for your applications, host systems, and individual network elements against exploitation of vulnerability-based threats as "single-bullet attacks," Trojan horses, worms, botnets, and surreptitious creation of "back doors" in your network.
- Protection against threats that exploit vulnerabilities in specific applications such as Web services, mail, DNS, SQL, and any Voice over IP (VoIP) services.
- Detection and elimination of spyware, phishing, and anonymizers (tools that hide a source computer's identifying information so that Internet activity can be undertaken surreptitiously).
- Protection against brute-force and DoS attacks, application scanning, and flooding.
- A regular method of updating threat lists and signatures.

Application Firewalls

Application firewalls (AFs) are sometimes confused with IPSs in that they can perform IPS-like functions. But an AF is specifically designed to limit or deny an application's level of access to a system's OS—in other words, closing any openings into a computer's OS to deny the execution of harmful code within an OS's structure. AFs work by looking at applications themselves, monitoring the kind of data flow from an application for suspicious or administrator-blocked content from specific Web sites, application-specific viruses, and any attempt to exploit an identified weakness in an application's architecture. Though AF systems can conduct intrusion prevention duties, they typically employ proxies to handle firewall access control and focus on traditional firewall-type functions. Application firewalls can detect the signatures of recognized threats and block them before they can infect the network.

Windows' version of an application firewall, called Data Execution Prevention (DEP), prevents the execution of any code that uses system services in such a way that could be deemed harmful to data or virtual memory (VM). It does this by considering RAM data as nonexecutable—in essence, refusing to run new code coming from the data-only area of RAM, since any harmful or malicious code seeking to damage existing data would have to run from this area.

The Macintosh Operating System (MacOS) also includes a built-in application firewall as a standard feature. The user can configure it to employ two-layer protection in which installing network-aware applications will result in an OS-generated warning that prompts for user authorization of network access. If authorized, MacOS will digitally sign the application in such a way that subsequent application activity will not prompt for further authorization. Updates invalidate the original certificate, and the user will have to revalidate before the application can run again.

The Linux OS has, for example, an application firewall called AppArmor that allows the administrator to create and link to every application a security policy that restricts its access capabilities.

Access Control Systems

Access control systems (ACSs) rely on administrator-defined rules that allow or restrict user access to protected network resources. These access rules can, for example, require strong user authentication such as tokens or biometric devices to prove the identity of users requesting access. They can also restrict access to various network services based on time of day or group need.

Some ACS products allow for the creation of an *access control list* (ACL), which is a set of rules that define security policy. These ACLs contain one or more *access control entries* (ACEs), which are the actual rule definitions themselves. These rules can restrict access by specific user, time of day, IP address, function (department, management level, etc.), or specific system from which a logon or access attempt is being made.

A good example of an ACS is SafeWord by Aladdin Knowledge Systems. SafeWord is considered a two-factor authentication system in that it uses what the user knows (such as a personal identification number, or PIN) and what the user has (such as a one-time passcode, or OTP, token) to strongly authenticate users requesting network access. SafeWord allows administrators to design customized access rules and restrictions to network resources, applications, and information.

In this scheme, the tokens are a key component. The token's internal cryptographic key algorithm is made "known" to an authentication server when the token's file is imported into a central database.

When the token is assigned to a user, its serial number is linked to that user in the user's record. On making an

access request, the authentication server prompts the user to enter a username and the OTP generated by the token. If a PIN was also assigned to that user, she must either prepend or append that PIN to the token-generated passcode. As long as the authentication server receives what it expects, the user is granted whatever access privileges she was assigned.

Unified Threat Management

The latest trend to emerge in the network intrusion prevention arena is referred to as *unified threat management*, or UTM. UTM systems are multilayered and incorporate several security technologies into a single platform, often in the form of a plug-in appliance. UTM products can provide such diverse capabilities as antivirus, VPN, firewall services, and antispam as well as intrusion prevention.

The biggest advantages of a UTM system are its ease of operation and configuration and the fact that its security features can be quickly updated to meet rapidly evolving threats.

Sidewinder by Secure Computing is a UTM system that was designed to be flexible, easily and quickly adaptable, and easy to manage. It incorporates firewall, VPN, trusted source, IPS, antispam and antivirus, URL filtering, SSL decryption, and auditing/reporting.

Other UTM systems include Symantec's Enterprise Firewall and Gateway Security Enterprise Firewall Appliance, Fortinet, LokTek's AIRlok Firewall Appliance, and SonicWall's NSA 240 UTM Appliance, to name a few.

12. CONTROLLING USER ACCESS

Traditionally users—also known as employees—have been the weakest link in a company's defensive armor. Though necessary to the organization, they can be a nightmare waiting to happen to your network. How do you let them work within the network while controlling their access to resources? You have to make sure your system of user authentication knows who your users are.

Authentication, Authorization, and Accounting

Authentication is simply proving that a user's identity claim is valid and authentic. Authentication requires some form of "proof of identity." In network technologies, physical proof (such as a driver's license or other photo ID) cannot be employed, so you have to get something else from a user. That typically means having the user respond to a challenge to provide genuine credentials at the time he or she requests access.

For our purposes, credentials can be something the user knows, something the user has, or something they are. Once they provide authentication, there also has to be authorization, or permission to enter. Finally, you want to have some record of users' entry into your network—username, time of entry, and resources. That is the accounting side of the process.

What the User Knows

Users know a great many details about their own lives—birthdays, anniversaries, first cars, their spouse's name—and many will try to use these nuggets of information as a simple form of authentication. What they don't realize is just how insecure those pieces of information are.

In network technologies, these pieces of information are often used as fixed passwords and PINs because they're easy to remember. Unless some strict guidelines are established on what form a password or PIN can take (for example, a minimum number of characters or a mixture of letters and numbers), a password will offer little to no real security.

Unfortunately, to hold down costs, some organizations allow users to set their own passwords and PINs as credentials, then rely on a simple challenge-response mechanism in which these weak credentials are provided to gain access. Adding to the loss of security is the fact that not only are the fixed passwords far too easy to guess, but because the user already has too much to remember, she writes them down somewhere near the computer she uses (often in some "cryptic" scheme to make it more difficult to guess). To increase the effectiveness of any security system, that system needs to require a much stronger form of authentication.

What the User Has

The most secure means of identifying users is by a combination of (1) a hardware device in their possession that is "known" to an authentication server in your network, coupled with (2) what they know. A whole host of devices available today—tokens, smart cards, biometric devices—are designed to more positively identify a user. Since a good token is the most secure of these options, let us focus on them here.

Tokens

A *token* is a device that employs an encrypted key for which the encryption algorithm—the method of generating an encrypted password—is known to a network's authentication server. There are both software and hardware tokens. The software tokens can be installed on a user's desktop system, in the cellular phone, or on the

smart phone. The hardware tokens come in a variety of form factors, some with a single button that both turns the token on and displays its internally generated passcode; others have a more elaborate numerical keypad for PIN input. If lost or stolen, tokens can easily be removed from the system, quickly rendering them completely ineffective. And the passcodes they generate are of the "one-time-passcode," or OTP, variety, meaning that a generated passcode expires once it's been used and cannot be used again for a subsequent logon attempt.

Tokens are either programmed onsite with token programming software or offsite at the time they are ordered from their vendor. During programming, functions such as a token's cryptographic key, password length, whether a PIN is required, and whether it generates passwords based on internal clock timing or user PIN input are written into the token's memory. When programming is complete, a file containing this information and the token's serial number are imported into the authentication server so that the token's characteristics are known.

A token is assigned to a user by linking its serial number to the user's record, stored in the system database. When a user logs onto the network and needs access to, say, her email, she is presented with some challenge that she must answer using her assigned token.

Tokens operate in one of three ways: time synchronous, event synchronous, or challenge-response (also known as asynchronous).

Time Synchronous

In time synchronous operations, the token's internal clock is synched with the network's clock. Each time the token's button is pressed, it generates a passcode in hash form, based on its internal timekeeping. As long as the token's clock is synched with the network clock, the passcodes are accepted. In some cases (for example, when the token hasn't been used for some time or its battery dies), the token gets out of synch with the system and needs to be resynched before it can be used again.

Event Synchronous

In event synchronous operations, the server maintains an ordered passcode sequence and determines which passcode is valid based on the current location in that sequence.

Challenge-Response

In challenge-response, a challenge, prompting for username, is issued to the user by the authentication server at the time of access request. Once the user's name is entered, the authentication server checks to see what form of authentication is assigned to that user and issues a challenge back to the user. The user inputs the challenge into the token, then enters the token's generated response to the challenge. As long as the authentication server receives what it expected, authentication is successful and access is granted.

The User is Authenticated, but is She/He Authorized?

Authorization is independent of authentication. A user can be permitted entry into the network but not be authorized to access a resource. You don't want an employee having access to HR information or a corporate partner getting access to confidential or proprietary information.

Authorization requires a set of rules that dictate the resources to which a user will have access. These permissions are established in your security policy.

Accounting

Say that our user has been granted access to the requested resource. But you want (or in some cases are required to have) the ability to call up and view activity logs to see who got into what resource. This information is mandated for organizations that deal with user financial or medical information or DoD classified information or that go through annual inspections to maintain certification for international operations.

Accounting refers to the recording, logging, and archiving of all server activity, especially activity related to access attempts and whether they were successful. This information should be written into audit logs that are stored and available any time you want or need to view them. The audit logs should contain, at minimum, the following information:

- The user's identity
- The date and time of the request
- Whether the request passed authentication and was granted

Any network security system you put into place should store, or archive, these logs for a specified period of time and allow you to determine for how long these archives will be maintained before they start to age out of the system.

Keeping Current

One of the best ways to stay ahead is to not fall behind in the first place. New systems with increasing sophistication are being developed all the time. They can incorporate a more intelligent and autonomous process in the way the system handles a detected threat, a faster and more easily accomplished method for updating threat

files, and configuration flexibility that allows for very precise customization of access rules, authentication requirements, user role assignment, and how tightly it can protect specific applications.

Register for newsletters, attend seminars and network security shows, read white papers, and, if needed, contract the services of network security specialists. The point is, you shouldn't go cheap on network security. The price you pay to keep ahead will be far less than the price you pay to recover from a security breach or attack.

Finally, let's briefly look at how host-based IPS agents offer various intrusion prevention capabilities. The following describes common intrusion prevention capabilities.

13. INTRUSION PREVENTION CAPABILITIES

As previously mentioned, host-based IPS agents offer various intrusion prevention capabilities. Because the capabilities vary based on the detection techniques used by each product, the following activities (see checklist: An Agenda for Action for Intrusion Prevention Activities") describe the capabilities by detection technique.

14. SUMMARY

This chapter has made it very apparent that preventing network intrusions is no easy task. Like cops on the street—usually outnumbered and underequipped compared to the bad guys—you face enemies with determination, skill, training, and a frightening array of increasingly sophisticated tools for hacking their way through your best defenses. And no matter how good your defenses are today, it's only a matter of time before a tool is developed that can penetrate them. If you know that ahead of time, you'll be much more inclined to keep a watchful eye for what "they" have and what you can use to defeat them.

Your best weapon is a logical, thoughtful, and nimble approach to network security. You have to be nimble—to evolve and grow with changes in technology, never being content to keep things as they are because "Hey, they're working just fine." Well, today's "just fine" will be tomorrow's "What the hell happened?"

Stay informed. There is no shortage of information available to you in the form of white papers, seminars, contract security specialists, and online resources, all dealing with various aspects of network security.

Invest in a good intrusion detection system. You want to know, as soon as possible, that a breach has occurred, what was stolen, and, if possible, where it went.

An Agenda for Action for Intrusion Prevention Activities

From the organizational perspective, preventing intrusions includes the following key activities (check all tasks completed):

_____1. **Code Analysis:** The code analysis techniques can prevent code from being executed, including malware and unauthorized applications.

_____2. **Network Traffic Analysis:** This can stop incoming network traffic from being processed by the host and outgoing network traffic from exiting it.

_____3. **Network Traffic Filtering:** Working as a host-based firewall, this can stop unauthorized access and acceptable use policy violations (use of inappropriate external services).

_____4. **Filesystem Monitoring:** This can prevent files from being accessed, modified, replaced, or deleted, which could stop malware installation, including Trojan horses and rootkits, as well as other attacks involving inappropriate file access.

______5. **Removable Media Restriction:** Some products can enforce restrictions on the use of removable media, both Universal Serial Bus (USB-based (flash drive)) and traditional (CD). This can prevent malware or other unwanted files from being transferred to a host and can also stop sensitive files from being copied from the host to removable media.

_____6. **Audiovisual Device Monitoring**: A few host-based IPS products can detect when a host's audiovisual devices, such as microphones, cameras, or IP-based phones, are activated or used. This could indicate that the host has been compromised by an attacker.

_____7. **Host Hardening**: Some host-based intrusion detection and prevention systems (IDPSs) can automatically harden hosts on an ongoing basis. For example, if an application is reconfigured, causing a particular security function to be disabled, the IDPS could detect this and enable the security function.

_____8. **Process Status Monitoring**: Some products monitor the status of processes or services running on a host, and if they detect that one has stopped, they restart it automatically. Some products can also monitor the status of security programs such as antivirus software.

_____9. **Network Traffic Sanitization**: Some agents, particularly those deployed on appliances, can sanitize the network traffic that they monitor. For example, an appliance-based agent could act as a proxy and rebuild each request and response that is directed through it. This can be effective at neutralizing certain unusual activity, particularly in packet headers and application protocol headers.

Have a good, solid, comprehensive, yet easy-to-understand network security policy in place. The very process of developing one will get all involved parties thinking about how to best secure your network while addressing user needs. When it comes to your users, you simply can't overeducate them where network security awareness is concerned. The more they know, the better equipped they'll be to act as allies against, rather than accomplices of, the hordes of crackers looking to steal, damage, hobble, or completely cripple your network.

Do your research and invest in good, multipurpose network security systems. Select systems that are easy to install and implement, are adaptable and quickly configurable, can be customized to suit your needs of today as well as tomorrow, and are supported by companies that keep pace with current trends in cracker technology.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? A network intrusion is an authorized penetration of your enterprise's network, or an individual machine address in your assigned domain.
2. True or False? In some cases, a network intrusion could be done from the inside by a disgruntled employee looking to hurt the organization or steal company secrets for profit.
3. True or False? Most security software products available today have two basic methods of spotting malicious software.
4. True or False? Crackers are going to first look for known strengths in the operating system (OS) or any applications you are using.
5. True or False? Finding a device, using it in a place (or manner) in which prying eyes can see passwords or data, awareness of hacking tools specifically designed to sniff wireless signals for data, and logging on to unsecured networks, are all potential problem areas with which users need to be familiar.

Multiple Choice

1. Which devices can locate wireless signals within a certain range, where they can siphon off the data being transmitted over the signals?
   - **A.** Wireless sniffers
   - **B.** Packet sniffers
   - **C.** Port scanners
   - **D.** Port knocking
   - **E.** Keystroke loggers
2. You can expect to have continued problems maintaining good network security awareness. Keep it simple. You need to draft some policies that define your network and its basic architecture. A good place to start is by asking the following questions, except which one?
   - **A.** What kinds of resources need to be protected (user financial or medical data, credit-card information, etc.)?
   - **B.** How many users will be accessing the network on the inside (employees, contractors, etc.)?
   - **C.** Will there need to be access only at certain times or on a 24/7 basis (and across multiple time zones and/or internationally)?
   - **D.** What kind of budget do I have?
   - **E.** Will internal users be accessing the network, and if so, how many?
3. A good IDS detects unauthorized intrusions using three types of models:
   - **A.** Anomaly-based
   - **B.** Signature-based
   - **C.** Network-based
   - **D.** Hybrid detection
   - **E.** Host-based
4. For an IPS to be effective, it must also be very good at discriminating between a real threat signature and one that looks like but isn't one (false positive). Once a signature interpreted to be an intrusion is detected, the system must quickly notify the administrator so that the appropriate evasive action can be taken. The following are types of IPS, except one:
   - **A.** Network-based
   - **B.** Rate-based
   - **C.** Host-based
   - **D.** Backdoor-based
   - **E.** Content-based
5. The latest trend to emerge in the network intrusion prevention arena is referred to as:
   - **A.** antivirus.
   - **B.** unified threat management.
   - **C.** VPN.
   - **D.** firewall services.
   - **E.** antispam.

EXERCISE

Problem

Determine how an information system could prevent nonprivileged users from circumventing intrusion prevention capabilities.

Hands-On Projects

Project

To safeguard its intellectual property and business, a pharmaceutical company had to keep pace with an increasingly sophisticated threat landscape of malware and viruses, as well as complex security legislation across its multiple sites. Please describe what type of intrusion prevention capabilities/services the company implemented.

Case Projects

Problem

A large medical center sought a powerful security solution that could continuously protect its high-throughput network without compromising network performance. It also required a healthy network: one that is safe from hackers, worms, viruses, and spyware, that can compromise the performance of the medical's life-critical applications or the federally mandated confidentiality of its medical records. In addition, the security system needed to be cost-effective and interoperate transparently with the medical center's multivendor infrastructure. In this case project, how would an intrusion prevention system (IPS) provide the pervasive and proactive protection that the medical center required?

Optional Team Case Project

Problem

With so much at stake, companies of all sizes are taking a closer look at intrusion prevention systems (IPSs) security solutions. In order to sift through the claims and separate the intrusion prevention contenders from the pretenders, the companies need to ask potential vendors a number of obvious basic questions first. Please list the basic IPS questions that a company might ask their vendors?

Chapter 5

Guarding Against Network Intrusions

Thomas M. Chen
Swansea University

Patrick J. Walsh
eSoft Inc.

Virtually all computers today are connected to the Internet through dialup, broadband, Ethernet, or wireless technologies. The reason for ubiquitous Internet connectivity is simple: Applications depending on the network, such as email, Web, remote login, instant messaging, social networking, and VoIP, have become essential to everyday computing. Unfortunately, the Internet exposes computer users to risks from a wide variety of possible threats. Users have much to lose—their privacy, valuable data, control of their computers, and possibly theft of their identities. The network enables attacks to be carried out remotely from anywhere in the world, with relative anonymity and low risk of traceability.

The nature of network intrusions has evolved over the years. A few years ago, a major concern was fast worms such as Code Red, Nimda, Slammer, and Sobig. More recently, concerns have shifted to spyware, Trojan horses, and botnets. Although these other threats = continue to be major problems, the Web has become the primary vector for stealthy attacks today.[1]

1. TRADITIONAL RECONNAISSANCE AND ATTACKS

Traditionally, attack methods follow sequential steps analogous to physical attacks, as shown in Figure 5.1: reconnaissance; compromise; and cover-up.[2] Here we are only addressing attacks directed at a specific target host. Some other types of attacks, such as worms or malicious Web sites, are not directed at specific targets. Instead, they attempt to hit as many targets as quickly as possible without caring about who or what the targets are.

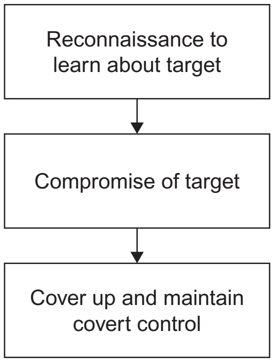

FIGURE 5.1 Steps in directed attacks.

In the first step of a directed attack, the attacker performs reconnaissance to learn as much as possible about the chosen target before carrying out an actual attack. A thorough reconnaissance can lead to a more effective attack because the target's weaknesses can be discovered. One might expect the reconnaissance phase to possibly tip off the target about an impending attack, but scans and probes are going on constantly in the "background noise" of Internet traffic, so systems administrators might ignore attack probes as too troublesome to investigate.

Through pings and traceroutes, an attacker can discover IP addresses and map the network around the target. Pings are ICMP echo request and echo reply messages that verify a host's IP address and availability. Traceroute is a network mapping utility that takes advantage of the time-to-live (TTL) field in IP packets. It sends out packets with TTL = 1, then TTL = 2, and so on. When the packets expire, the routers along the packets' path report that the packets have been discarded, returning ICMP "time exceeded" messages and thereby allowing the traceroute utility to learn the IP addresses of routers at a distance of one hop, two hops, and so on.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00005-2

Port scans can reveal open ports. Normally, a host might be expected to have certain well-known ports open, such as TCP port 80 (HTTP), TCP port 21 (FTP), TCP port 23 (Telnet), or TCP port 25 (SMTP). A host might also happen to have open ports in the higher range. For example, port 12345 is the default port used by the Netbus remote access Trojan horse, or port 31337 is the default port used by the Back Orifice remote access Trojan horse. Discovery of ports indicating previous malware infections could obviously help an attacker considerably.

In addition to discovering open ports, the popular NMAP scanner (www.insecure.org/nmap) can discover the operating system running on a target. NMAP uses a large set of heuristic rules to identify an operating system based on a target's responses to carefully crafted TCP/IP probes. The basic idea is that different operating systems will make different responses to probes to open TCP/UDP ports and malformed TCP/IP packets. Knowledge of a target's operating system can help an attacker identify vulnerabilities and find effective exploits.

Vulnerability scanning tests a target for the presence of vulnerabilities. Vulnerability scanners such as SATAN, SARA, SAINT, and Nessus typically contain a database of known vulnerabilities that is used to craft probes to a chosen target. The popular Nessus tool (www.nessus.org) has an extensible plug-in architecture to add checks for backdoors, misconfiguration errors, default accounts and passwords, and other types of vulnerabilities.

In the second step of a directed attack, the attacker attempts to compromise the target through one or more methods. Password attacks are common because passwords might be based on common words or names and are guessable by a dictionary attack, although computer systems today have better password policies that forbid easily guessable passwords. If an attacker can obtain the password file from the target, numerous password-cracking tools are available to carry out a brute-force password attack. In addition, computers and networking equipment often ship with default accounts and passwords intended to help systems administrators set up the equipment. These default accounts and passwords are easy to find on the Web (for example, www.phenoelit-us.org/dpl/dpl.html). Occasionally, users might neglect to change or delete the default accounts, offering intruders an easy way to access the target.

Another common attack method is an exploit attack code written to take advantage of a specific vulnerability.[3] Many types of software, including operating systems and applications, have vulnerabilities. Symantec discovered 6253 vulnerabilities in 2010, or 17 vulnerabilities per day on average.[4] Vulnerabilities are published by several organizations such as CERT and MITRE, as well as vendors such as Microsoft, through security bulletins. MITRE maintains a database of publicly known vulnerabilities identified by common vulnerabilities and exposures (CVE) numbers. The severity of vulnerabilities is reflected in the industry-standard common vulnerability scoring system (CVSS). In the first half of 2011, Microsoft observed that 44 percent of vulnerabilities were highly severe, 49 percent were medium-severe, and 7 percent were low-severe.[5] Furthermore, about 45 percent of vulnerabilities were easily exploitable.

Historically, buffer overflows have been the most common type of vulnerability.[6] They have been popular because buffer overflow exploits can often be carried out remotely and lead to complete compromise of a target. The problem arises when a program has allocated a fixed amount of memory space (such as in the stack) for storing data but receives more data than expected. If the vulnerability exists, the extra data will overwrite adjacent parts of memory, which could mess up other variables or pointers. If the extra data is random, the computer might crash or act unpredictably. However, if an attacker crafts the extra data carefully, the buffer overflow could overwrite adjacent memory in a way that benefits the attacker. For instance, an attacker might overwrite the return pointer in a stack, causing the program control to jump to malicious code inserted by the attacker.

An effective buffer overflow exploit requires technical knowledge of the computer architecture and operating system, but once the exploit code is written, it can be reused. Buffer overflows can be prevented by the programmer or compiler performing bounds checking or during runtime. Although C/C++ has received a good deal of blame as a programming language for not having built-in checking that data written to arrays stays within bounds, buffer overflow vulnerabilities appear in a wide variety of other programs, too.

Structured Query Language (SQL) injection is a type of vulnerability relevant to Web servers with a database backend.[7] SQL is an internationally standardized interactive and programming language for querying data and managing databases. Many commercial database products support SQL, sometimes with proprietary extensions. Web applications often take user input (usually from a Web form) and pass the input into an SQL statement. An

7 D. Litchfield, *SQL Server Security*, McGraw-Hill Osborne, 2003.

SQL injection vulnerability can arise if user input is not properly filtered for string literal escape characters, which can allow an attacker to craft input that is interpreted as embedded SQL statements and thereby manipulate the application running on the database.

Servers have been attacked and compromised by toolkits designed to automate customized attacks. For example, the MPack toolkit emerged in early 2007 and is sold commercially in Russia, along with technical support and regular software updates. It is loaded into a malicious or compromised Web site. When a visitor goes to the site, a malicious code is launched through an iframe (inline frame) within the HTML code. It can launch various exploits, expandable through modules, for vulnerabilities in Web browsers and client software.

Metasploit (www.metasploit.com) is a popular Perl-based tool for developing and using exploits with an easy-to-use Web or command-line interface. Different exploits can be written and loaded into Metasploit and then directed at a chosen target. Exploits can be bundled with a payload (the code to run on a compromised target) selected from a collection of payloads. The tool also contains utilities to experiment with new vulnerabilities and help automate the development of new exploits.

Although exploits are commonplace, not all attacks require an exploit. *Social engineering* refers to types of attacks that take advantage of human nature to compromise a target, typically through deceit. A common social engineering attack is *phishing*, used in identity theft.[8] Phishing starts with a lure, usually a spam message that appears to be from a legitimate bank or e-commerce business. The message attempts to provoke the reader into visiting a fraudulent Web site pretending to be a legitimate business. These fraudulent sites are often set up by automated phishing toolkits that spoof legitimate sites of various brands, including the graphics of those brands. The fraudulent site might even have links to the legitimate Web site, to appear more valid. Victims are thus tricked into submitting valuable personal information such as account numbers, passwords, and Social Security numbers.

Other common examples of social engineering are spam messages that entice the reader into opening an email attachment. Most people know by now that attachments could be dangerous, perhaps containing a virus or spyware, even if they appear to be innocent at first glance. But if the message is sufficiently convincing, such as appearing to originate from an acquaintance, even wary users might be tricked into opening an attachment. Social engineering attacks can be simple but effective because they target people and bypass technological defenses.

The third step of traditional directed attacks involves cover-up of evidence of the compromise and establishment of covert control. After a successful attack, intruders want to maintain remote control and evade detection. Remote control can be maintained if the attacker has managed to install any of a number of types of malicious software: a backdoor such as Netcat; a remote access Trojan such as BO2K or SubSeven; or a bot, usually listening for remote instructions on an Internet relay chat (IRC) channel, such as phatbot.

Intruders obviously prefer to evade detection after a successful compromise, because detection will lead the victim to take remedial actions to harden or disinfect the target. Intruders might change the system logs on the target, which will likely contain evidence of their attack. In Windows, the main event logs are secevent.evt, sysevent.evt, and appevent.evt. A systems administrator looking for evidence of intrusions would look in these files with the built-in Windows Event Viewer or a third-party log viewer. An intelligent intruder would not delete the logs but would selectively delete information in the logs to hide signs of malicious actions.

A *rootkit* is a stealthy type of malicious software (*malware*) designed to hide the existence of certain processes or programs from normal methods of detection.[9] Rootkits essentially alter the target's operating system, perhaps by changing drivers or dynamic link libraries (DLLs) and possibly at the kernel level. An example is the kernel-mode FU rootkit that manipulates kernel memory in Windows 2000, XP, and 2003. It consists of a device driver, msdirectx.sys, that might be mistaken for Microsoft's DirectX tool. The rootkit can hide certain events and processes and change the privileges of running processes.

If an intruder has installed malware for covert control, he will want to conceal the communications between himself and the compromised target from discovery by network-based *intrusion detection systems* (IDSs). Intrusion detection systems are designed to listen to network traffic and look for signs of suspicious activities. Several concealment methods are used in practice. *Tunneling* is a commonly used method to place packets of one protocol into the payload of another packet. The "exterior" packet serves a vehicle to carry and deliver the "interior" packet intact. Though the protocol of the exterior packet is easily understood by an IDS, the interior protocol can be any number of possibilities and hence difficult to interpret.

Encryption is another obvious concealment method. Encryption relies on the secrecy of an encryption key

8. Markus Jakobsson and Steven Meyers, eds., *Phishing and Countermeasures: Understanding the Increasing Problem of Electronic Identity Theft*, Wiley-Interscience, 2006.

9. Greg Hoglund and Jamie Butler, *Rootkits: Subverting the Windows Kernel*, Addison-Wesley Professional, 2005.

shared between the intruder and the compromised target. The encryption key is used to mathematically scramble the communications into a form that is unreadable without the key to decrypt it. Encryption ensures secrecy in practical terms but does not guarantee perfect security. Encryption keys can be guessed, but the time to guess the correct key increases exponentially with the key length. Long keys combined with an algorithm for periodically changing keys can ensure that encrypted communications will be difficult to break within a reasonable time.

Fragmentation of IP packets is another means to conceal the contents of messages from IDSs, which often do not bother to reassemble fragments. IP packets may normally be fragmented into smaller packets anywhere along a route and reassembled at the destination. An IDS can become confused with a flood of fragments, bogus fragments, or deliberately overlapping fragments.

2. MALICIOUS SOFTWARE

Malicious software, or malware, continues to be an enormous problem for Internet users because of its variety and prevalence and the level of danger it presents.[10,11,12] It is important to realize that malware can take many forms. A large class of malware is *infectious*, which includes viruses and worms. Viruses and worms are self-replicating, meaning that they spread from host to host by making copies of themselves. Viruses are pieces of code attached to a normal file or program. When the program is run, the virus code is executed and copies itself to (or infects) another file or program. It is often said that viruses need a human action to spread, whereas worms are standalone automated programs. Worms look for vulnerable targets across the network and transfer a copy of themselves if a target is successfully compromised.

Historically, several worms have become well known and stimulated concerns over the possibility of a fast epidemic infecting Internet-connected hosts before defenses could stop it. The 1988 Robert Morris Jr. worm infected thousands of Unix hosts, at the time a significant portion of the Arpanet (the predecessor to the Internet). The 1999 Melissa worm infected Microsoft Word documents and emailed itself to addresses found in a victim's Outlook address book. Melissa demonstrated that email could be a very effective vector for malware distribution, and many subsequent worms have continued to use email, such as the 2000 Love Letter worm. In the 2001−2004 interval, several fast worms appeared, notably Code Red, Nimda, Klez, SQL Slammer/Sapphire, Blaster, Sobig, and MyDoom.

An important feature of viruses and worms is their capability to carry a *payload*—malicious code that is executed on a compromised host. The payload can be virtually anything. For instance, SQL Slammer/Sapphire had no payload, whereas Code Red carried an agent to perform a denial-of-service (DoS) attack on certain fixed addresses. The Chernobyl or CIH virus had one of the most destructive payloads, attempting to overwrite critical system files and the system BIOS that is needed for a computer to boot up. Worms are sometimes used to deliver other malware, such as bots, in their payload. They are popular delivery vehicles because of their ability to spread by themselves and carry anything in their payload.

Members of a second large class of malware are characterized by attempts to conceal themselves. This class includes Trojan horses and rootkits. Worms are not particularly stealthy (unless they are designed to be) because they are typically indiscriminate in their attacks. They probe potential targets in the hope of compromising many targets quickly. Indeed, fast-spreading worms are relatively easy to detect because of the network congestion caused by their probes.

Stealth is an important feature for malware because the critical problem for antivirus software is obviously detection of malware. Trojan horses are a type of malware that appears to perform a useful function but hides a malicious function. Thus, the presence of the Trojan horse might not be concealed, but functionality is not fully revealed. For example, a video codec could offer to play certain types of video but also covertly steal the user's data in the background. In the second half of 2007, Microsoft reported a dramatic increase of 300 percent% in the number of Trojan downloaders and droppers, small programs to facilitate downloading more malware later.[4]

Rootkits are essentially modifications to the operating system to hide the presence of files or processes from normal means of detection. Rootkits are often installed as drivers or kernel modules. A highly publicized example was the extended copy protection (XCP) software included in some Sony BMG audio CDs in 2005, to prevent music copying. The software was installed automatically on Windows PCs when a CD was played. Made by a company called First 4 Internet, XCP unfortunately contained a hidden rootkit component that patched the operating system to prevent it from displaying any processes, Registry entries, or files with names beginning with *sys*. Although the intention of XCP was not malicious, there was concern that the rootkit could be used by malware writers to conceal malware.

A third important class of malware is designed for remote control. This class includes remote access Trojans

10. David Harley and David Slade, *Viruses Revealed*, McGraw-Hill, 2001.

11. Ed Skoudis, *Malware: Fighting Malicious Code*, Prentice Hall PTR, 2004.

12. Peter Szor, *The Art of Computer Virus Research and Defense*, Addison-Wesley, 2005.

(RATs) and bots. Instead of *remote access Trojan*, RAT is sometimes interpreted as *remote administration tool* because it can be used for legitimate purposes by systems administrators. Either way, RAT refers to a type of software usually consisting of server and client parts designed to enable covert communications with a remote controller. The client part is installed on a victim host and mainly listens for instructions from the server part, located at the controller. Notorious examples include Back Orifice, Netbus, and Sub7.

Bots are remote-control programs installed covertly on innocent hosts.[13] Bots are typically programmed to listen to IRC channels for instructions from a "bot herder." All bots under control of the same bot herder form a botnet. Botnets have been known to be rented out for purposes of sending spam or launching a distributed DoS (DDoS) attack.[14] The power of a botnet is proportional to its size, but exact sizes have been difficult to discover.

One of the most publicized bots is the Storm worm, which has various aliases. Storm was launched in January 2007 as spam with a Trojan horse attachment. As a botnet, Storm has shown unusual resilience by working in a distributed peer-to-peer manner without centralized control. Each compromised host connects to a small subset of the entire botnet. Each infected host shares lists of other infected hosts, but no single host has a full list of the entire botnet. The size of the Storm botnet has been estimated at more than 1 million compromised hosts, but an exact size has been impossible to determine because of the many bot variants and active measures to avoid detection. Its creators have been persistent in continually updating its lures with current events and evolving tactics to spread and avoid detection.

Another major class of malware is designed for data theft. This class includes keyloggers and spyware. A keylogger can be a Trojan horse or other form of malware. It is designed to record a user's keystrokes and perhaps report them to a remote attacker. Keyloggers are planted by criminals on unsuspecting hosts to steal passwords and other valuable personal information. It has also been rumored that the Federal Bureau of Investigation (FBI) has used a keylogger called Magic Lantern.

As the name implies, *spyware* is stealthy software designed to monitor and report user activities for the purposes of learning personal information without the user's knowledge or consent. Surveys have found that spyware is widely prevalent on consumer PCs, usually without knowledge of the owners. Adware is viewed by some as a mildly objectionable form of spyware that spies on Web browsing behavior to target online advertisements to a user's apparent interests. More objectionable forms of spyware are more invasive of privacy and raise other objections related to stealthy installation, interference with normal Web browsing, and difficulty of removal.

Spyware can be installed in a number of stealthy ways: disguised as a Trojan horse, bundled with a legitimate software program, delivered in the payload of a worm or virus, or downloaded through deception. For instance, a deceptive Web site might pop up a window appearing to be a standard Windows dialog box, but clicking any button will cause spyware to be downloaded. Another issue is that spyware might or might not display an end-user license agreement (EULA) before installation. If an EULA is displayed, the mention of spyware is typically unnoticeable or difficult to find.

More pernicious forms of spyware can change computer settings, reset homepages, and redirect the browser to unwanted sites. For example, the notorious CoolWebSearch changed homepages to Coolwebsearch.com, rewrote search engine results, and altered host files, and some variants added links to pornographic and gambling sites to the browser's bookmarks.

Lures and "Pull" Attacks

Traditional network attacks can be viewed as an "active" approach in which the attacker takes the initiative of a series of actions directed at a target. Attackers face the risk of revealing their malicious intentions through these actions. For instance, port scanning, password guessing, or exploit attempts can be readily detected by an IDS as suspicious activities. Sending malware through email can only be seen as an attempted attack.

Security researchers have observed a trend away from direct attacks toward stealthier attacks that wait for victims to visit malicious Web sites, as shown in Figure 5.2.[15] The Web has become the primary vector for infecting computers, in large part because email has become better secured. Sophos discovers a new malicious Webpage every 14 seconds, on average.[16]

Web-based attacks have significant advantages for attackers. First, they are stealthier and not as "noisy" as active attacks, making it easier to continue undetected for a longer time. Second, Web servers have the intelligence to be stealthy. For instance, Web servers have been found that serve up an attack only once per IP address and

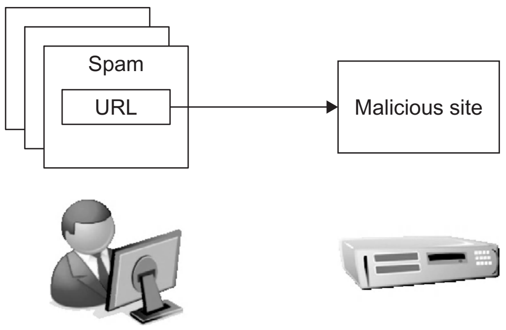

FIGURE 5.2 Stealthy attacks lure victims to malicious servers.

otherwise serve up legitimate content. The malicious server remembers the IP addresses of visitors. Thus, a visitor will be attacked only once, which makes the attack harder to detect. Third, a Web server can serve up different attacks, depending on the visitor's operating system and browser.

As mentioned earlier, a common type of attack carried out through the Web is phishing. A phishing site is typically disguised as a legitimate financial organization or e-commerce business. During the month of June 2011, the Anti-Phishing Working Group found 28,148 new unique phishing sites hijacking 310 brands (www.anti-phishing.org).

Another type of Web-based attack is a malicious site that attempts to download malware through a visitor's browser, called a *drive-by download*. A Web page usually loads a malicious script by means of an iframe (inline frame). It has been reported that most drive-by downloads are hosted on legitimate sites that have been compromised. For example, in June 2007 more than 10,000 legitimate Italian Web sites were discovered to be compromised with malicious code loaded through iframes. Many other legitimate sites are regularly compromised.

Drive-by downloading through a legitimate site holds certain appeal for attackers. First, most users will be reluctant to visit suspicious and potentially malicious sites but will not hesitate to visit legitimate sites in the belief that they are always safe. Even wary Web surfers may be caught off-guard. Second, the vast majority of Web servers run Apache (approximately 50 percent) or Microsoft IIS (approximately 40 percent), both of which have vulnerabilities that can be exploited by attackers. Moreover, servers with database applications could be vulnerable to SQL injection attacks. Third, if a legitimate site is compromised with an iframe, the malicious code might go unnoticed by the site owner for some time.

Pull-based attacks pose one challenge to attackers: They must somehow attract visitors to the malicious site, while avoiding detection by security researchers. One obvious option is to send out lures in spam. Lures have been disguised as email from the Internal Revenue Service, a security update from Microsoft, or a greeting card. The email attempts to entice the reader to visit a link. On one hand, lures are easier to get through spam filters because they only contain links and not attachments. It is easier for spam filters to detect malware attachments than to determine whether links in email are malicious. On the other hand, spam filters are easily capable of extracting and following links from spam. The greater challenge is to determine whether the linked site is malicious.

3. DEFENSE IN DEPTH

Most security experts would agree that perfect network security is impossible to achieve and that any single defense can always be overcome by an attacker with sufficient resources and motivation. The basic idea behind the *defense-in-depth strategy* is to hinder the attacker as much as possible with multiple layers of defense, even though each layer might be surmountable. More valuable assets should be protected behind more layers of defense. The combination of multiple layers increases the cost for the attacker to be successful, and the cost is proportional to the value of the protected assets. Moreover, a combination of multiple layers will be more effective against unpredictable attacks than will a single defense optimized for a particular type of attack.

The cost for the attacker could be in terms of additional time, effort, or equipment. For instance, by delaying an attacker, an organization would increase the chances of detecting and reacting to an attack in progress. The increased costs to an attacker could deter some attempts if the costs are believed to outweigh the possible gain from a successful attack.

Defense in depth is sometimes said to involve people, technology, and operations. Trained security people should be responsible for securing facilities and information assurance. However, every computer user in an organization should be made aware of security policies and practices. Every Internet user at home should be aware of safe practices (such as avoiding opening email attachments or clicking suspicious links) and the benefits of appropriate protection (antivirus software, firewalls).

A variety of technological measures can be used for layers of protection. These should include firewalls, IDSs, routers with ACLs, antivirus software, access control, spam filters, and so on. These topics are discussed in more depth later in this chapter.

The term *operations* refers to all preventive and reactive activities required to maintain security. Preventive activities include vulnerability assessments, software patching, system hardening (closing unnecessary ports),

and access controls. Reactive activities should detect malicious activities and react by blocking attacks, isolating valuable resources, or tracing the intruder.

Protection of valuable assets can be a more complicated decision than simply considering the value of the assets. Organizations often perform a risk assessment to determine the value of assets, possible threats, likelihood of threats, and possible impact of threats. Valuable assets facing unlikely threats or threats with low impact might not need much protection. Clearly, assets of high value facing likely threats or high-impact threats merit the strongest defenses. Organizations usually have their own risk management process for identifying risks and deciding how to allocate a security budget to protect valuable assets under risk.

4. PREVENTIVE MEASURES

Most computer users are aware that Internet connectivity comes with security risks. It would be reasonable to take precautions to minimize exposure to attacks. Fortunately, several options are available to computer users to fortify their systems to reduce risks.

Access Control

In computer security, *access control* refers to mechanisms to allow users to perform functions up to their authorized level and restrict users from performing unauthorized functions.[17] Access control includes:

- Authentication of users
- Authorization of their privileges
- Auditing to monitor and record user actions

All computer users will be familiar with some type of access control.

Authentication, the process of verifying a user's identity, is typically based on one or more of these factors:

- Something the user knows, such as a password or PIN
- Something the user has, such as a smart card or token
- Something personal about the user, such as a fingerprint, retinal pattern, or other biometric identifier

Use of a single factor, even if multiple pieces of evidence are offered, is considered weak authentication. A combination of two factors, such as a password and a fingerprint, called *two-factor* (or *multifactor*) *authentication*, is considered strong authentication.

Authorization is the process of determining what an authenticated user can do. Most operating systems have an established set of permissions related to read, write, or execute access. For example, an ordinary user might have permission to read a certain file but not write to it, whereas a root or superuser will have full privileges to do anything.

Auditing is necessary to ensure that users are accountable. Computer systems record actions in the system in audit trails and logs. For security purposes, they are invaluable forensic tools to re-create and analyze incidents. For instance, a user attempting numerous failed logins might be seen as an intruder.

Vulnerability Testing and Patching

As mentioned earlier, vulnerabilities are weaknesses in software that might be used to compromise a computer. Vulnerable software includes all types of operating systems and application programs. New vulnerabilities are being discovered constantly in different ways. New vulnerabilities discovered by security researchers are usually reported confidentially to the vendor, which is given time to study the vulnerability and develop a path. Of all vulnerabilities disclosed in 2007, 50 percent could be corrected through vendor patches.[18] When ready, the vendor will publish the vulnerability, hopefully along with a patch.

It has been argued that publication of vulnerabilities will help attackers. Although this might be true, publication also fosters awareness within the entire community. Systems administrators will be able to evaluate their systems and take appropriate precautions. One might expect systems administrators to know the configuration of computers on their network, but in large organizations, it would be difficult to keep track of possible configuration changes made by users. Vulnerability testing offers a simple way to learn about the configuration of computers on a network.

Vulnerability testing is an exercise to probe systems for known vulnerabilities. It requires a database of known vulnerabilities, a packet generator, and test routines to generate a sequence of packets to test for a particular vulnerability. If a vulnerability is found and a software patch is available, that host should be patched.

Penetration testing is a closely related idea but takes it further. Penetration testing simulates the actions of a hypothetical attacker to attempt to compromise hosts. The goal is, again, to learn about weaknesses in the network so that they can be remedied.

Closing Ports

Transport layer protocols, namely, Transmission Control Protocol (TCP) and User Datagram Protocol (UDP),

17. B. Carroll, Cisco Access Control Security: AAA Administration Services, Cisco Press, 2004.

18. IBM Internet Security Systems, *X-Force 2007 Trend Statistics*, January 2008 (date of access: July 1, 2008).

identify applications communicating with each other by means of port numbers. Port numbers 1 to 1023 are well known and assigned by the Internet Assigned Numbers Authority (IANA) to standardized services running with root privileges. For example, Web servers listen on TCP port 80 for client requests. Port numbers 1024 to 49151 are used by various applications with ordinary user privileges. Port numbers above 49151 are used dynamically by applications.

It is good practice to close ports that are unnecessary, because attackers can use open ports, particularly those in the higher range. For instance, the Sub7 Trojan horse is known to use port 27374 by default, and Netbus uses port 12345. Closing ports does not by itself guarantee the safety of a host, however. Some hosts need to keep TCP port 80 open for HyperText Transfer Protocol (HTTP), but attacks can still be carried out through that port.

Firewalls

When most people think of network security, firewalls are one of the first things to come to mind. Firewalls are a means of perimeter security protecting an internal network from external threats. A firewall selectively allows or blocks incoming and outgoing traffic. Firewalls can be standalone network devices located at the entry to a private network or personal firewall programs running on PCs. An organization's firewall protects the internal community; a personal firewall can be customized to an individual's needs.

Firewalls can provide separation and isolation among various network zones, namely, the public Internet, private intranets, and a demilitarized zone (DMZ), as shown in Figure 5.3. The semiprotected DMZ typically includes public services provided by a private organization. Public servers need some protection from the public Internet, so they usually sit behind a firewall. This firewall cannot be completely restrictive because the public servers must be externally accessible. Another firewall typically sits between the DMZ and private internal network because the internal network needs additional protection.

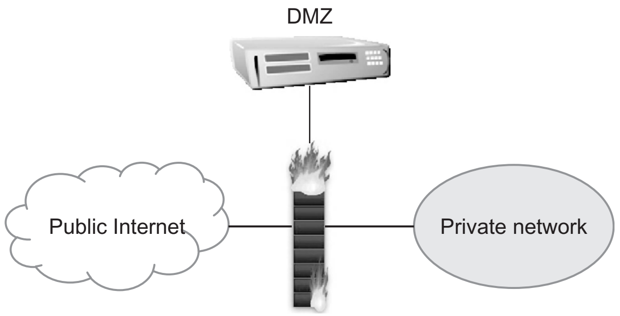

FIGURE 5.3 A firewall isolating various network zones.

There are various types of firewalls: packet-filtering firewalls, stateful firewalls, and proxy firewalls. In any case, the effectiveness of a firewall depends on the configuration of its rules. Properly written rules require detailed knowledge of network protocols. Unfortunately, some firewalls are improperly configured through neglect or lack of training.

Packet-filtering firewalls analyze packets in both directions and either permit or deny passage based on a set of rules. Rules typically examine port numbers, protocols, IP addresses, and other attributes of packet headers. There is no attempt to relate multiple packets with a flow or stream. The firewall is stateless, retaining no memory of one packet to the next.

Stateful firewalls overcome the limitation of packet-filtering firewalls by recognizing packets belonging to the same flow or connection and keeping track of the connection state. They work at the network layer and recognize the legitimacy of sessions.

Proxy firewalls are also called application-level firewalls because they process up to the application layer. They recognize certain applications and can detect whether an undesirable protocol is using a nonstandard port or an application layer protocol is being abused. They protect an internal network by serving as primary gateways to proxy connections from the internal network to the public Internet. They could have some impact on network performance due to the nature of the analysis.

Firewalls are essential elements of an overall defensive strategy but have the drawback that they only protect the perimeter. They are useless if an intruder has a way to bypass the perimeter. They are also useless against insider threats originating within a private network.

Antivirus and Antispyware Tools

The proliferation of malware prompts the need for antivirus software.[19] Antivirus software is developed to detect the presence of malware, identify its nature, remove the malware (disinfect the host), and protect a host from future infections. Detection should ideally minimize false positives (false alarms) and false negatives (missed malware) at the same time. Antivirus software faces a number of difficult challenges:

- Malware tactics are sophisticated and constantly evolving.
- Even the operating system on infected hosts cannot be trusted.
- Malware can exist entirely in memory without affecting files.

19. Peter Szor, *The Art of Computer Virus Research and Defense*, Addison-Wesley, 2005.

- Malware can attack antivirus processes.
- The processing load for antivirus software cannot degrade computer performance such that users become annoyed and turn the antivirus software off.

One of the simplest tasks performed by antivirus software is file scanning. This process compares the bytes in files with known signatures that are byte patterns indicative of a known malware. It represents the general approach of signature-based detection. When new malware is captured, it is analyzed for unique characteristics that can be described in a signature. The new signature is distributed as updates to antivirus programs. Antivirus looks for the signature during file scanning, and if a match is found, the signature identifies the malware specifically. There are major drawbacks to this method, however: New signatures require time to develop and test; users must keep their signature files up to date; and new malware without a known signature may escape detection.

Behavior-based detection is a complementary approach. Instead of addressing what malware is, behavior-based detection looks at what malware tries to do. In other words, anything attempting a risky action will come under suspicion. This approach overcomes the limitations of signature-based detection and could find new malware without a signature, just from its behavior. However, the approach can be difficult in practice. First, we must define what is suspicious behavior, or conversely, what is normal behavior. This definition often relies on heuristic rules developed by security experts, because normal behavior is difficult to define precisely. Second, it might be possible to *discern* suspicious behavior, but it is much more difficult to *determine* malicious behavior, because malicious intention must be inferred. When behavior-based detection flags suspicious behavior, more follow-up investigation is usually needed to better understand the threat risk.

The ability of malware to change or disguise appearances can defeat file scanning. However, regardless of its form, malware must ultimately perform its mission. Thus, an opportunity will always arise to detect malware from its behavior if it is given a chance to execute. Antivirus software will monitor system events, such as hard-disk access, to look for actions that might pose a threat to the host. Events are monitored by intercepting calls to operating system functions.

Although monitoring system events is a step beyond file scanning, malicious programs are running in the host execution environment and could pose a risk to the host. The idea of emulation is to execute suspected code within an isolated environment, presenting the appearance of the computer resources to the code, and to look for actions symptomatic of malware.

Virtualization takes emulation a step further and executes suspected code within a real operating system. A number of virtual operating systems can run above the host operating system. Malware can corrupt a virtual operating system, but for safety reasons a virtual operating system has limited access to the host operating system. A "sandbox" isolates the virtual environment from tampering with the host environment, unless a specific action is requested and permitted. In contrast, emulation does not offer an operating system to suspected code; the code is allowed to execute step by step, but in a controlled and restricted way, just to discover what it will attempt to do.

Antispyware software can be viewed as a specialized class of antivirus software. Somewhat unlike traditional viruses, spyware can be particularly pernicious in making a vast number of changes throughout the hard drive and system files. Infected systems tend to have a large number of installed spyware programs, possibly including certain cookies (pieces of text planted by Web sites in the browser as a means of keeping them in memory).

Spam Filtering

Every Internet user is familiar with spam email. There is no consensus on an exact definition of spam, but most people would agree that spam is unsolicited, sent in bulk, and commercial in nature. There is also consensus that the vast majority of email is spam. Spam continues to be a problem because a small fraction of recipients do respond to these messages. Even though the fraction is small, the revenue generated is enough to make spam profitable because it costs little to send spam in bulk. In particular, a large botnet can generate an enormous amount of spam quickly.

Users of popular Webmail services such as Yahoo! and Hotmail are attractive targets for spam because their addresses might be easy to guess. In addition, spammers harvest email addresses from various sources: Web sites, newsgroups, online directories, data-stealing viruses, and so on. Spammers might also purchase lists of addresses from companies that are willing to sell customer information.

Spam is more than an inconvenience for users and a waste of network resources. Spam is a popular vehicle to distribute malware and lures to malicious Web sites. It is the first step in phishing attacks.

Spam filters work at an enterprise level and a personal level. At the enterprise level, mail gateways can protect an entire organization by scanning incoming messages for malware and blocking messages from suspicious or fake senders. A concern at the enterprise level is the rate of false positives, which are legitimate messages mistaken for spam. Users may become upset if their legitimate

mail is blocked. Fortunately, spam filters are typically customizable, and the rate of false positives can be made very low. Additional spam filtering at the personal level can customize filtering even further, to account for individual preferences.

Various spam-filtering techniques are embodied in many commercial and free spam filters, such as DSPAM and SpamAssassin, to name two. Bayesian filtering is one of the more popular techniques.[20] First, an incoming message is parsed into tokens, which are single words or word combinations from the message's header and body. Second, probabilities are assigned to tokens through a training process. The filter looks at a set of known spam messages compared to a set of known legitimate messages and calculates token probabilities based on Bayes' theorem (from probability theory). Intuitively, a word such as *Viagra* would appear more often in spam, and therefore the appearance of a Viagra token would increase the probability of that message being classified as spam.

The probability calculated for a message is compared to a chosen threshold; if the probability is higher, the message is classified as spam. The threshold is chosen to balance the rates of false positives and false negatives (missed spam) in some desired way. An attractive feature of Bayesian filtering is that its probabilities will adapt to new spam tactics, given continual feedback, that is, correction of false positives and false negatives by the user.

It is easy to see why spammers have attacked Bayesian filters by attempting to influence the probabilities of tokens. For example, spammers have tried filling messages with large amounts of legitimate text (e.g., drawn from classic literature) or random innocuous words. The presence of legitimate tokens tends to decrease a message's score because they are evidence counted toward the legitimacy of the message.

Spammers are continually trying new ways to get through spam filters. At the same time, security companies respond by adapting their technologies.

Honeypots

The basic idea of a *honeypot* is to learn about attacker techniques by attracting attacks to a seemingly vulnerable host.[21] It is essentially a forensics tool rather than a line of defense. A honeypot could be used to gain valuable information about attack methods used elsewhere or imminent attacks before they happen. Honeypots are used routinely in research and production environments.

A honeypot has more special requirements than a regular PC. First, a honeypot should not be used for legitimate services or traffic. Consequently, every activity seen by the honeypot will be illegitimate. Even though honeypots typically record little data compared to IDS, for instance, their data has little "noise," whereas the bulk of IDS data is typically uninteresting from a security point of view.

Second, a honeypot should have comprehensive and reliable capabilities for monitoring and logging all activities. The forensic value of a honeypot depends on the detailed information it can capture about attacks.

Third, a honeypot should be isolated from the real network. Since honeypots are intended to attract attacks, there is a real risk that the honeypot could be compromised and used as a launching pad to attack more hosts in the network.

Honeypots are often classified according to their level of interaction, ranging from low to high. Low-interaction honeypots, such as Honeyd, offer the appearance of simple services. An attacker could try to compromise the honeypot but would not have much to gain. The limited interactions pose a risk that an attacker could discover that the host is a honeypot. At the other end of the range, high-interaction honeypots behave more like real systems. They have more capabilities to interact with an attacker and log activities, but they offer more to gain if they are compromised.

Honeypots are related to the concepts of black holes or network telescopes, which are monitored blocks of unused IP addresses. Since the addresses are unused, any traffic seen at those addresses is naturally suspicious (though not necessarily malicious).

Traditional honeypots suffer a drawback in that they are passive and wait to see malicious activity. The idea of honeypots has been extended to active clients that search for malicious servers and interact with them. The active version of a honeypot has been called a *honey-monkey* or *client honeypot*.

Network Access Control

A vulnerable host might place not only itself but an entire community at risk. For one thing, a vulnerable host might attract attacks. If compromised, the host could be used to launch attacks on other hosts. The compromised host might give information to the attacker, or there might be trust relationships between hosts that could help the attacker. In any case, it is not desirable to have a weakly protected host on your network.

The general idea of *network access control* (NAC) is to restrict a host from accessing a network unless the host can provide evidence of a strong security posture. The NAC process involves the host, the network (usually

20. J. Zdziarski, *Ending Spam: Bayesian Content Filtering and the Art of Statistical Language Classification*, No Starch Press, 2005.

21. The Honeynet Project, *Know Your Enemy: Learning about Security Threats*, 2nd ed., Addison-Wesley, 2004.

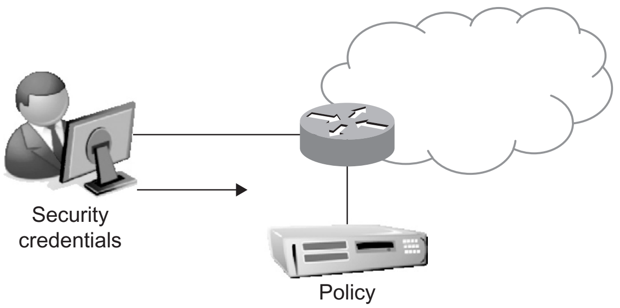

FIGURE 5.4 Network access control.

routers or switches, and servers), and a security policy, as shown in Figure 5.4.

The details of the NAC process vary with various implementations, which unfortunately currently lack standards for interoperability. A host's security posture includes its IP address, operating system, antivirus software, personal firewall, and host intrusion detection system. In some implementations, a software agent runs on the host, collects information about the host's security posture, and reports it to the network as part of a request for admission to the network. The network refers to a policy server to compare the host's security posture to the security policy, to make an admission decision.

The admission decision could be anything from rejection to partial admission or full admission. Rejection might be prompted by out-of-date antivirus software, an operating system needing patches, or firewall misconfiguration. Rejection might lead to quarantine (routing to an isolated network) or forced remediation.

5. INTRUSION MONITORING AND DETECTION

Preventive measures are necessary and help reduce the risk of attacks, but it is practically impossible to prevent all attacks. Intrusion detection is also necessary to detect and diagnose malicious activities, analogous to a burglar alarm. Intrusion detection is essentially a combination of monitoring, analysis, and response.[22] Typically, an IDS supports a console for human interface and display. Monitoring and analysis are usually viewed as passive techniques because they do not interfere with ongoing activities. The typical IDS response is an alert to systems administrators, who may or may not choose to pursue further investigation. In other words, traditional IDSs do not offer much response beyond alerts, under the presumption that security incidents need human expertise and judgment for follow-up.

22. Richard Bejtlich, *The Tao of Network Security Monitoring: Beyond Intrusion Detection*, Addison-Wesley, 2005.

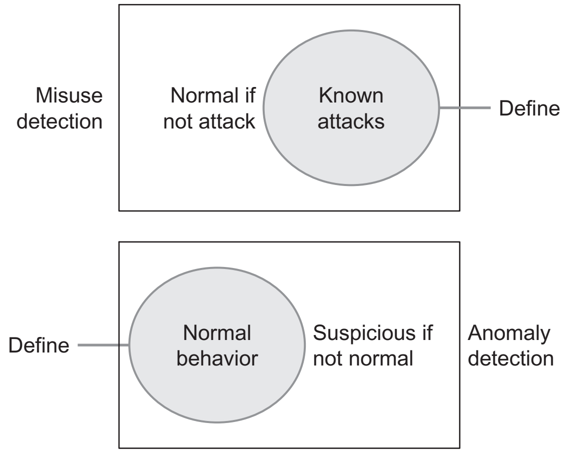

FIGURE 5.5 Misuse detection and anomaly detection.

Detection accuracy is the critical problem for intrusion detection. Intrusion detection should ideally minimize false positives (normal incidents mistaken for suspicious ones) and false negatives (malicious incidents escaping detection). Naturally, false negatives are contrary to the essential purpose of intrusion detection. False positives are also harmful because they are troublesome for systems administrators who must waste time investigating false alarms. Intrusion detection should also seek to more than identify security incidents. In addition to relating the facts of an incident, intrusion detection should ascertain the nature of the incident, the perpetrator, the seriousness (malicious vs. suspicious), scope, and potential consequences (such as stepping from one target to more targets).

IDS approaches can be categorized in at least two ways. One way is to differentiate host-based and network-based IDS, depending on where sensing is done. A host-based IDS monitors an individual host, whereas a network-based IDS works on network packets. Another way to view IDS is by their approach to analysis. Traditionally, the two analysis approaches are misuse (signature-based) detection and anomaly (behavior-based) detection. As shown in Figure 5.5, these two views are complementary and are often used in combination.

In practice, intrusion detection faces several difficult challenges: Signature-based detection can recognize only incidents matching a known signature; behavior-based detection relies on an understanding of normal behavior, but "normal" can vary widely. Attackers are intelligent and evasive; attackers might try to confuse IDS with fragmented, encrypted, tunneled, or junk packets; an IDS might not react to an incident in real time or quickly enough to stop an attack; and incidents can occur anywhere at any time, which necessitates continual and extensive monitoring, with correlation of multiple distributed sensors.

Host-Based Monitoring

Host-based IDS runs on a host and monitors system activities for signs of suspicious behavior. Examples could be changes to the system Registry, repeated failed login attempts, or installation of a backdoor. Host-based IDSs usually monitor system objects, processes, and regions of memory. For each system object, the IDS will usually keep track of attributes such as permissions, size, modification dates, and hashed contents, to recognize changes.

A concern for a host-based IDS is possible tampering by an attacker. If an attacker gains control of a system, the IDS cannot be trusted. Hence, special protection of the IDS against tampering should be architected into a host.

A host-based IDS is not a complete solution by itself. Although monitoring the host is logical, it has three significant drawbacks: Visibility is limited to a single host; the IDS process consumes resources, possibly impacting performance on the host; and attacks will not be seen until they have already reached the host. Host-based and network-based IDS are often used together to combine strengths.

Traffic Monitoring

Network-based IDSs typically monitor network packets for signs of reconnaissance, exploits, DoS attacks, and malware. They have strengths to complement host-based IDSs: Network-based IDSs can see traffic for a population of hosts; they can recognize patterns shared by multiple hosts; and they have the potential to see attacks before they reach the hosts.

IDSs are placed in various locations for different views, as shown in Figure 5.6. An IDS outside a firewall is useful for learning about malicious activities on the Internet. An IDS in the DMZ will see attacks originating from the Internet that are able to get through the outer firewall to public servers. Lastly, an IDS in the private network is necessary to detect any attacks that are able to successfully penetrate perimeter security.

Signature-Based Detection

Signature-based intrusion detection depends on patterns that uniquely identify an attack. If an incident matches a known signature, the signature identifies the specific attack. The central issue is how to define signatures or model attacks. If signatures are too specific, a change in an attack tactic could result in a false negative (missed alarm). An attack signature should be broad enough to cover an entire class of attacks. On the other hand, if signatures are too general, it can result in false positives.

Signature-based approaches have three inherent drawbacks: New attacks can be missed if a matching signature is not known; signatures require time to develop for new attacks; and new signatures must be distributed continually.

Snort is a popular example of a signature-based IDS (www.snort.org). Snort signatures are rules that define fields that match packets of information about the represented attack. Snort is packaged with more than 1800 rules covering a broad range of attacks, and new rules are constantly being written.

Behavior Anomalies

A behavior-based IDS is appealing for its potential to recognize new attacks without a known signature. It presumes that attacks will be different from normal behavior. Hence the critical issue is how to define normal behavior, and anything outside of normal (anomalous) is classified as suspicious. A common approach is to define normal behavior in statistical terms, which allows for deviations within a range.

Behavior-based approaches have considerable challenges. First, normal behavior is based on past behavior. Thus, data about past behavior must be available for training the IDS. Second, behavior can and does change over time, so any IDS approach must be adaptive. Third, anomalies are just unusual events, not necessarily malicious ones. A behavior-based IDS might point out

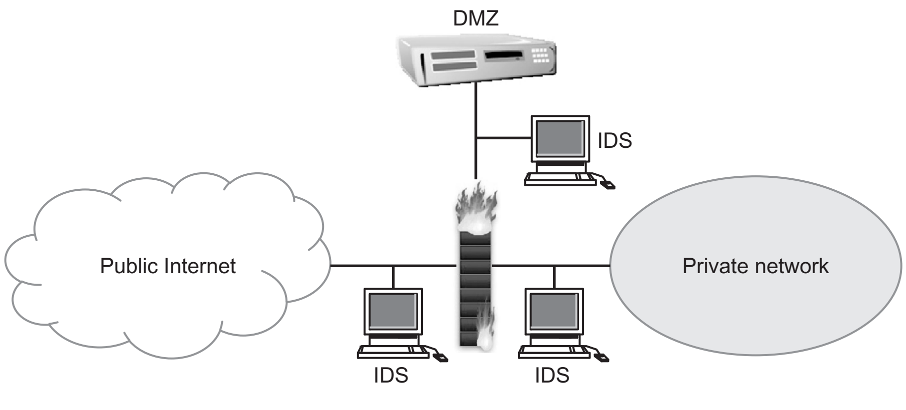

FIGURE 5.6 IDSs monitoring various network zones.

incidents to investigate further, but it is not good at discerning the exact nature of attacks.

Intrusion Prevention Systems

IDSs are passive techniques. They typically notify the systems administrator to investigate further and take the appropriate action. The response might be slow if the systems administrator is busy or the incident is time consuming to investigate.

A variation called an *intrusion prevention system* (IPS) seeks to combine the traditional monitoring and analysis functions of an IDS with more active automated responses, such as automatically reconfiguring firewalls to block an attack. An IPS aims for a faster response than humans can achieve, but its accuracy depends on the same techniques as the traditional IDS. The response should not harm legitimate traffic, so accuracy is critical.

6. REACTIVE MEASURES

When an attack is detected and analyzed, systems administrators must exercise an appropriate response to the attack. One of the principles in security is that the response should be proportional to the threat. Obviously, the response will depend on the circumstances, but various options are available. Generally, it is possible to block, slow, modify, or redirect any malicious traffic. It is not possible to delineate every possible response. Here we describe only two responses: quarantine and traceback.

Quarantine

Dynamic quarantine in computer security is analogous to quarantine for infectious diseases. It is an appropriate response, particularly in the context of malware, to prevent an infected host from contaminating other hosts. Infectious malware requires connectivity between an infected host and a new target, so it is logical to disrupt the connectivity between hosts or networks as a means to impede the malware from spreading further.

Within the network, traffic can be blocked by firewalls or routers with access control lists (ACLs). ACLs are similar to firewall rules, allowing routers to selectively drop packets.

Traceback

One of the critical aspects of an attack is the identity or location of the perpetrator. Unfortunately, discovery of an attacker in IP networks is almost impossible because:

- The source address in IP packets can be easily spoofed (forged).
- Routers are stateless by design and do not keep records of forwarded packets.
- Attackers can use a series of intermediary hosts (called *stepping stones* or *zombies*) to carry out their attacks.

Intermediaries are usually innocent computers taken over by an exploit or malware and put under control of the attacker. In practice, it might be possible to trace an attack back to the closest intermediary, but it might be too much to expect to trace an attack all the way back to the real attacker.

To trace a packet's route, some tracking information must be either stored at routers when the packet is forwarded or carried in the packet, as shown in Figure 5.7. An example of the first approach is to store a hash of a packet for some amount of time. If an attack occurs, the target host will query routers for a hash of the attack packet. If a router has the hash, it is evidence that the packet had been forwarded by that router. To reduce memory consumption, the hash is stored instead of storing

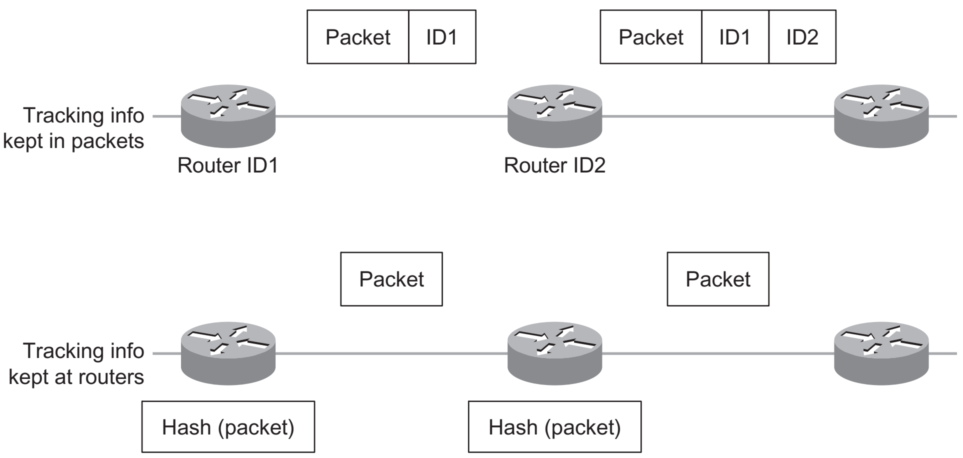

FIGURE 5.7 Tracking information stored at routers or carried in packets to enable packet traceback.

An Agenda for Action for Logging Capabilities Activities

As previously stated, network-based IPSs typically perform extensive logging of data related to detected events. This data can be used to confirm the validity of alerts, to investigate incidents, and to correlate events between the IPS and other logging sources. Data fields commonly logged by network-based IPSs include the following key activities (check all tasks completed):

_____**1.** Timestamp (usually date and time).

_____**2.** Connection or session ID (typically a consecutive or unique number assigned to each TCP connection or to like groups of packets for connectionless protocols).

_____**3.** Event or alert type. In the console, the event or alert type often links to supporting information for the specific vulnerability or exploit, such as references for additional information and associated Common Vulnerabilities and Exposures (CVE) numbers.

_____**4.** Rating (priority, severity, impact, confidence).

_____**5.** Network, transport, and application layer protocols.

_____**6.** Source and destination IP addresses.

_____**7.** Source and destination TCP or UDP ports, or ICMP types and codes.

_____**8.** Number of bytes transmitted over the connection.

_____**9.** Decoded payload data, such as application requests and responses.

_____**10.** State-related information (authenticated username).

_____**11.** Prevention action performed (if any).

the entire packet. The storage is temporary instead of permanent so that routers will not run out of memory.

An example of the second approach is to stamp packets with a unique router identifier, such as an IP address. Thus the packet carries a record of its route. The main advantage here is that routers can remain stateless. The problem is that there is no space in the IP packet header for this scheme.

Finally, let's briefly look at how a network-based intrusion protection system (IPS) monitors network traffic for particular network segments or devices and analyzes network, transport, and application protocols to identify suspicious activity. The following section describes common intrusion protection components.

7. NETWORK-BASED INTRUSION PROTECTION

Network-based IPS components are similar to other types of IPS technologies, except for the sensors. A network-based IPS sensor monitors and analyzes network activity on one or more network segments. Sensors are available in two formats: appliance-based sensors, which are comprised of specialized hardware and software optimized for IPS sensor use, and software-only sensors, which can be installed onto hosts that meet certain specifications.

Network-based IPSs also provide a wide variety of security capabilities. Some products can collect information on hosts such as which OSs they use and which application versions they use that communicate over networks. Network-based IPSs can also perform extensive logging of data related to detected events (see checklist: An Agenda for Action for Logging Capabilities Activities); most can also perform packet captures.

8. SUMMARY

This chapter made it perfectly clear that, to guard against network intrusions, we must understand the variety of attacks, from exploits to malware to social engineering. Direct attacks are prevalent, but a class of *pull attacks* has emerged, relying on lures to bring victims to a malicious Web site. Pull attacks are much more difficult to uncover and in a way defend against. Just about anyone can become victimized.

Much can be done to fortify hosts and reduce their risk exposure, but some attacks are unavoidable. Defense in depth is a most practical defense strategy, combining layers of defenses. Although each defensive layer is imperfect, the cost becomes harder to surmount for intruders.

One of the essential defenses is *intrusion detection*. Host-based and network-based intrusion detection systems have their respective strengths and weaknesses. Research continues to be needed to improve intrusion detection, particularly behavior-based techniques. As more attacks are invented, signature-based techniques will have more difficulty keeping up.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Traditionally, attack methods do not follow sequential steps analogous to physical attacks.
2. True or False? Malicious software, or malware, is not an enormous problem for Internet users because of its

variety and prevalence and the level of danger it presents.
3. True or False? Traditional network attacks can be viewed as an "active" approach in which the attacker takes the initiative of a series of actions directed at a target.
4. True or False? The basic idea behind the *defense-in-depth strategy* is to hinder the attacker as much as possible with multiple layers of defense, even though each layer might be surmountable.
5. True or False? In computer security, *access control* refers to mechanisms to allow users to perform functions up to their unauthorized level and restrict users from performing authorized functions.

Multiple Choice

1. A stealthy type of malicious software (*malware*) designed to hide the existence of certain processes or programs from normal methods of detection is known as a:
   - **A.** wireless sniffer.
   - **B.** rootkit.
   - **C.** port scanner.
   - **D.** port knocker.
   - **E.** keystroke logger.
2. If an intruder has installed malware for covert control, he or she will want to conceal the communications between him- or herself and the compromised target from discovery by:
   - **A.** network-based intrusion detection systems (IDSs).
   - **B.** tunneling.
   - **C.** multiple time zones.
   - **D.** budgets.
   - **E.** networks.
3. What is a commonly used method to place packets of one protocol into the payload of another packet?
   - **A.** Encryption
   - **B.** Signature-based
   - **C.** Tunneling
   - **D.** Hybrid detection
   - **E.** Host-based
4. What is another obvious concealment method?
   - **A.** Infection
   - **B.** Rate
   - **C.** Host
   - **D.** Back door
   - **E.** Encryption
5. What can be a Trojan horse or other form of malware?
   - **A.** Antivirus
   - **B.** Unified threat management
   - **C.** Keylogger
   - **D.** Firewall
   - **E.** Antispam

EXERCISE

Problem

A physical security company has an innovative, patented product and critical secrets to protect. For this company, protecting physical security and safeguarding network security go hand-in-hand. A Web application in the data center tracks the serialized keycodes and allows customers to manage their key sets. The customers include everyone from theft-conscious retail chains to security-sensitive government agencies. In this case project, how would the security company go about establishing solid network security to protect them against intrusions?

Hands-On Projects

Project

A solution services company is also a managed service provider specializing in IT infrastructure, Voice over Internet Protocol (VoIP), wireless broadband, data centers, and procurement. As part of a customer network security upgrade, how would the company go about establishing a solid network to protect a school district's network from external threats; as well as the risk of unauthorized intrusions by users within the network?

Case Projects

Problem

For a international town's 10-person IT staff, upgrading its network security initiative meant expanding its multivendor Gigabit and Fast Ethernet network and ensuring that its growing volume of e-government services, including online tax payments, license application filings, and housing services, function without network intrusions. To accomplish this purpose, how would the town go about guarding against increasing waves of computer viruses, malware, and denial-ofservice (DoS) attacks?

Optional Team Case Project

Problem

Intrusion types of systems are put in place to serve business needs for meeting an objective of network security; IDSs and IPSs provide a foundation of technology needs and for tracking; and, identifying network attacks which detect intrusions through logs of IDS systems and preventing an action through IPS systems. If a company hosts critical systems, confidential data, and strict compliance regulations, then it's great to use IDS or IPS or both in guarding network environments. So, what are the basic benefits of IDS and IPS systems?

Chapter 6

Securing Cloud Computing Systems

Cem Gurkok
Verizon Terremark

1. CLOUD COMPUTING ESSENTIALS: EXAMINING THE CLOUD LAYERS

Cloud computing is composed of several layers, such as public, private, hybrid, and community deployment models: SaaS, PaaS, IaaS (service, platform, infrastructure as a service or SPI) service models. The NIST Model of Cloud Computing is shown in Figure 6.1.

Infrastructure as a service (IaaS) provides online processing, data storage capacity, or network capacity on a virtualized environment. It offers the ability to provision processing, storage, networks, and other basic computing resources, allowing the customer to install and run their software, which can involve operating systems (OSs) and applications. IaaS customers buy these resources as a fully outsourced service. IaaS provides a set of application programming interfaces, which allows management and other forms of interaction with the infrastructure by consumers. Amazon, Terremark, and Rackspace are typical IaaS providers.

Platform as a service (PaaS) sits on top of IaaS. It provides an application development and deployment environment in the cloud. PaaS offers the ability to deploy applications by utilizing computer programming languages and tools available from the service provider. The service provider offers developers application building blocks to configure a new business application. This provides all of the facilities required to support the complete life cycle of building and delivering Web applications and services entirely available from the Internet. Google App Engine, Microsoft Azure, Engine Yard and Collabnet are some PaaS providers.

Service as a service (SaaS) is built on IaaS and PaaS. It serves business applications utilized by individuals or enterprises, and it can also be referred to as on-demand software. SaaS offers the most popular cloud applications to almost everyone that is online. Salesforce.com, Google Docs, and Microsoft Online Services are all popular consumer and enterprise-directed SaaS applications. The applications are accessible from various client devices through a thin client interface such as a Web browser.

Analyzing Cloud Options in Depth

Table 6.1 shows us that different cloud deployment models have varying management, ownership, locations, and access levels.

Public

Public cloud is an offering from one service provider to many clients who share the cloud-processing resources concurrently. Public cloud clients share applications,

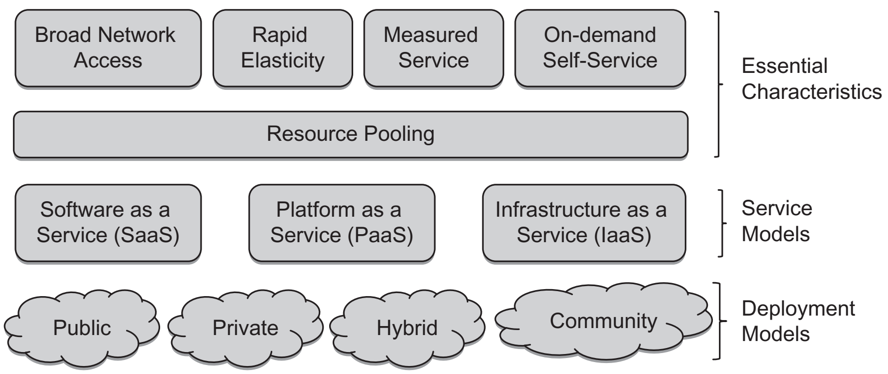

FIGURE 6.1 NIST model of cloud computing [1].

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00006-4

TABLE 6.1 Deployment Model's Responsibilities.

Model/Infrastructure	Managed by	Owned by	Location	Used by
Public	External CSP	External CSP	Off-Site	Untrusted
Private	Customer or external CSP	Customer or external CSP	On-site or off-site	Trusted
Hybrid	Customer and external CSP	Customer and external CSP	On-site and off-site	Trusted and untrusted

Note: CSP, Cloud Service Provider.

processing power, network resources, and data storage space. Differing levels of segregation are provided depending on the resource.

Private

A private cloud hosts one enterprise as a user. Various departments may be present in the cloud, but all are in the same enterprise. Private clouds often employ virtualization within an enterprise's existing computer servers to improve computer utilization. A private cloud also includes provisioning and metering facilities that enable fast deployment and removal where applicable. This model is similar to the conventional IT outsourcing models, but can also exist as an enterprise's internal delivery model. A variety of private cloud implementations have emerged:

- *Dedicated private cloud*: These are hosted within a customer-owned data center or at a collocation facility, and are operated by internal IT departments.
- *Community private cloud*: These are located at the premises of a third party and are owned, managed, and operated by a vendor who is bound by customized service-level agreements (SLAs) and contractual clauses with security and compliance requirements.
- *Managed private cloud*: In this implementation, the infrastructure is owned by the customer and management is performed by a third party.

Virtual Private

A virtual private cloud is a private cloud that exists within a shared or public cloud also called the Intercloud. The Intercloud comprises several interconnected clouds and legacy infrastructure. Amazon Web Services provides Amazon Virtual Private Cloud, which allows the Amazon Elastic Compute Cloud service to be connected to legacy infrastructure over an IPsec virtual private network connection. Google App Engine provides similar functionality via their Secure Data Connector product.

Hybrid

A hybrid cloud is a combination of two or more of the previously mentioned deployment models. Each of the three cloud deployment models has specific advantages and disadvantages relative to the other deployment models. A hybrid cloud leverages the advantage of the other cloud models, providing a more optimal user experience. By utilizing the hybrid cloud architecture, users are able to obtain degrees of fault tolerance combined with locally immediate usability without dependency on Internet connectivity.

Establishing Cloud Security Fundamentals

Security in cloud computing, for the most part, is no different than security in a regular IT environment. However, due to the different deployment models as described above, cloud environments present different risks to an organization.The European Network and Information Security Agency (ENISA) generally groups the risks into policy and organizational, technical, legal, and general risks and describes them as follows [2]:

Policy and Organizational Risks

Let's look at the following policy and organizational risks:

- Lock-in
- Loss of governance
- Compliance challenges
- Loss of business reputation due to co-tenant activities
- Cloud service termination or failure
- Cloud provider acquisition
- Supply chain failure

Lock-in

The potential dependency on a particular cloud provider, depending on the provider's commitments, may lead to a catastrophic business failure, should the cloud provider go bankrupt or the content and application migration path

to another provider become too costly. There is little or no incentive for cloud providers to make migrating to another provider easy if they are not contractually bound to do so.

Loss of Governance

By using cloud infrastructures, the client necessarily cedes control to the cloud provider on a number of issues that may affect security. This could have a severe impact on the organization's strategy and therefore on the capacity to meet its mission and goals. The loss of control and governance could lead to the impossibility of complying with the security requirements, a lack of confidentiality, integrity and availability of data, and a deterioration of performance and quality of service, not to mention the introduction of compliance challenges.

Compliance Challenges

Certain companies migrating to the cloud might need to meet certain industry standards or regulatory requirements, such as Payment Card Industry (PCI) Data Security Standard (DSS). Migrating to the cloud could compromise these business needs if the cloud provider cannot furnish evidence of its own compliance to the relevant requirements or if the provider does not permit audits by the customer.

Loss of Business Reputation Due to Co-tenant Activities

Resource sharing can give rise to problems when the shared resources' reputation becomes tainted by a bad neighbor's activities. This would also include that certain measures be taken to mitigate, such as IP address blocking and equipment confiscation.

Cloud Service Termination or Failure

If the cloud provider faces the risk of going out of business due to financial, legal, or other reasons, the customer could suffer from loss or deterioration of service delivery performance and quality of service; as well as loss of investment.

Cloud Provider Acquisition

The acquisition of the cloud provider could increase the possibility of a strategic change and could put previous agreements at risk. This could make it impossible to comply with existing security requirements. The final impact could be damaging for crucial assets, such as the organization's reputation, customer or patient trust, and employee loyalty and experience.

Supply Chain Failure

A cloud computing provider can outsource certain specialized tasks of its infrastructure to third parties. In such a situation, the cloud provider's level of security may depend on the level of security of each one of the links and the level of dependency of the cloud provider on the third party. In general, lack of transparency in the contract can be a problem for the whole system.

Technical Risks

Let's continue now by taking a look at the following technical risks:

- Resource exhaustion
- Resource segregation failure
- Abuse of high-privilege roles
- Management interface compromise
- Intercepting data in transit, data leakage
- Insecure deletion of data
- Distributed denial of service (DDoS)
- Economic denial of service (EDoS)
- Encryption and key management (loss of encryption keys)
- Undertaking malicious probes or scans
- Compromise of the service engine
- Customer requirements and cloud environment conflicts

Resource Exhaustion

Inaccurate modeling of customer demands by the cloud provider can lead to service unavailability, access control compromise, and economic and reputation losses due to resource exhaustion. The customer takes a level of calculated risk in allocating all the resources of a cloud service because resources are allocated according to statistical projections.

Resource Segregation Failure

This class of risks includes the failure of mechanisms separating storage, memory, routing, and even reputation between different tenants of the shared infrastructure (guest-hopping attacks, SQL injection attacks exposing multiple customers' data, and side-channel attacks). The likelihood of this incident scenario depends on the cloud model adopted by the customer. It is less likely to occur for private cloud customers compared to public cloud customers.

Abuse of High Privilege Roles

The malicious activities of an insider could potentially have an impact on the confidentiality, integrity, and availability of all kinds of data, on all kinds of services, and therefore

indirectly on the organization's reputation, customer trust, and employee experiences. This can be considered especially important in the case of cloud computing due to the fact that cloud architectures necessitate certain roles, which are extremely high risk. Examples of such roles include the cloud provider's system administrators and auditors and managed security service providers dealing with intrusion detection reports and incident response.

Management Interface Compromise

The customer management interfaces of public cloud providers are Internet accessible and mediate access to larger sets of resources (than traditional hosting providers). They also pose an increased risk, especially when combined with remote access and Web browser vulnerabilities.

Intercepting Data in Transit, Data Leakage

Cloud computing, being a distributed architecture, implies more data is in transit than with traditional infrastructures. Sniffing, spoofing, man-in—the-middle attacks, side channel, and replay attacks should be considered as possible threat sources.

Insecure Deletion of Data

Whenever a provider is changed, resources are scaled down, physical hardware is reallocated, and data may be available beyond the lifetime specified in the security policy. Where true data wiping is required, special procedures must be followed, and this may not be supported by the cloud provider.

Distributed Denial of Dervice (DDoS)

A common method of attack involves saturating the target environment with external communications requests, such that it cannot respond to legitimate traffic, or responds so slowly as to be rendered effectively unavailable. This can result in financial and economic losses.

Economic Denial of Service (EDoS)

EDoS destroys economic resources; the worst-case scenario would be the bankruptcy of the customer or a serious economic impact. The following scenarios are possible: An attacker can use an account and the customer's resources for his own gain or in order to damage the customer economically. The customer has not set effective limits on the use of paid resources and experiences unexpected loads on these resources. An attacker can use a public channel to deplete the customer's metered resources. For example, where the customer pays per HTTP request, a DDoS attack can have this effect.

Encryption and Key Management (Loss of Encryption Keys)

This risk includes the disclosure of secret keys (Secure Socket Layer [SSL], file encryption, customer private keys) or passwords to malicious parties. It also includes the loss or corruption of those keys, or their unauthorized use for authentication and no-repudiation (digital signature).

Undertaking Malicious Probes or Scans

Malicious probes or scanning, as well as network mapping, are indirect threats to the assets being considered. They can be used to collect information in the context of a hacking attempt. A possible impact could be a loss of confidentiality, integrity, and availability of service and data.

Compromise of the Service Engine

Each cloud architecture relies on a highly specialized platform and the service engine. The service engine sits above the physical hardware resources and manages customer resources at different levels of abstraction. For example, in IaaS clouds this software component can be the hypervisor. Like any other software layer, the service engine code can have vulnerabilities and is prone to attacks or unexpected failure. Cloud providers must set out a clear segregation of responsibilities that articulate the minimum actions customers must undertake.

Customer Requirements and Cloud Environment Conflicts

Cloud providers must set out a clear segregation of responsibilities that specify the minimum actions customers must undertake. The failure of the customers to properly secure their environments may pose a vulnerability to the cloud platform if the cloud provider has not taken the necessary steps to provide isolation. Cloud providers should further articulate their isolation mechanisms and provide best practice guidelines to assist customers in securing their resources.

Legal Risks

Now, let's look at the following legal risks:

- Subpoena and e-discovery
- Varying jurisdiction
- Data protection
- Licensing

Subpoena and e-discovery

In the event of the confiscation of physical hardware as a result of subpoena by law enforcement agencies or civil

suits, the centralization of storage as well as shared tenancy of physical hardware means that many more clients are at risk of the disclosure of their data to unwanted parties. At the same time, it may become impossible for the agency of a single nation to confiscate "a cloud," given pending advances around long-distance hypervisor migration.

Varying Jurisdiction

Customer data may be held in multiple jurisdictions, some of which may be high risk or subject to higher restrictions. Certain countries are regarded as high risk because of their unpredictable legal frameworks and disrespect of international agreements. In these cases customer data can be accessed by various parties without the customer's consent. On the other hand, other countries can have stricter privacy laws and might require that certain data cannot be stored or tracked.

Data Protection

It has to be clear that the cloud customer will be the main person responsible for processing personal data, even when such processing is carried out by the cloud provider in its role of external processor. While some cloud providers, such as SAS 70-compliant ones, provide information about their data processing and security activities, others are opaque about these activities and can cause legal problems for the customer. There may also be data security breaches that are not notified to the controller by the cloud provider. In some cases, customers might be storing illegal or illegally obtained data, which might put the cloud provider and other customers at risk.

Licensing

Licensing conditions, such as per-seat agreements, and online licensing checks may become unworkable in a cloud environment. For example, if software is charged on a per-instance basis every time a new machine is instantiated, then the cloud customer's licensing costs may increase exponentially, even though they are using the same number of machine instances for the same duration.

General Risks

Let's continue by looking at the following general risks:

- Network failures
- Privilege escalation
- Social engineering
- Loss or compromise of operational and security logs or audit trails
- Backup loss
- Unauthorized physical access and theft of equipment
- Natural disasters

Network Failures

Network failure is one of the highest risks since it directly affects service delivery. It exists due to network misconfiguration, system vulnerabilities, lack of resource isolation, and poor or untested business continuity and disaster recovery plans. Network traffic modification can also be a risk for a customer and cloud provider; if provisioning isn't done properly, there is no traffic encryption or vulnerability assessment.

Privilege Escalation

Although this risk has a low probability of exploitation, it can cause loss of customer data and access control. A malicious entity can therefore take control of large portions of the cloud platform. The risk manifests itself owing to authentication, authorization, and other access control vulnerabilities, hypervisor vulnerabilities (cloud bursting), and misconfiguration.

Social Engineering

This risk is one of the most disregarded risks since most technical staff focuses on the nonhuman aspects of their platforms. The exploitation of this risk has caused loss of reputation for cloud service providers, such as Amazon and Apple due to the publicity of the events. This risk can be easily minimized by security awareness training, proper user provisioning, resource isolation, data encryption, and proper physical security procedures.

Loss or Compromise of Operational and Security Logs or Audit Trails

Operational logs can be vulnerable due to lack of policy or poor procedures for log collection. This would also include retention, access management vulnerabilities, user deprovisioning vulnerabilities, lack of forensic readiness, and operating system vulnerabilities.

Backup Loss

This high-impact risk affects company reputation, all backed up data, and service delivery. It also occurs owing to inadequate physical security procedures, access management vulnerabilities, and user deprovisioning vulnerabilities.

Unauthorized Physical Access and Theft of Equipment

The probability of malicious actors gaining access to a physical location is very low, but in the event of such an occurrence, the impact to the cloud provider and its customers is very high. It can affect company reputation and data hosted on premises; the risk is due to inadequate physical security procedures.

Natural Disasters

This risk is another ignored risk that can have a high impact on the businesses involved in the event of its occurrence. If a business has a poor or an untested business continuity and disaster recovery plan or lacks one, its reputation, data, and service delivery can be severely compromised.

Other Cloud Security Concepts

Finally, let's look at the following cloud security concepts:

- Incident response (IR), notification, and remediation
- Virtualization
- External accreditations

Incident Response (IR), Notification and Remediation

Incident response comprises a set of procedures for an investigator to examine a computer security incident. Although cloud computing brings change on many levels, certain characteristics of cloud computing pose more direct challenges to IR activities than others. The on-demand self-service nature of cloud computing environments makes it hard or even impossible to receive cooperation from the cloud service provider when handling a security incident. Also, the resource pooling practiced by cloud services, in addition to the rapid elasticity offered by cloud infrastructures, may dramatically complicate the IR process, especially the forensic activities carried out as part of the incident analysis. Resource pooling as practiced by cloud services causes privacy concerns for co-tenants regarding the collection and analysis of telemetry and artifacts associated with an incident (e.g., logging, netflow data, memory, machine images) without compromising the privacy of co-tenants. The cross-border nature of cloud computing might cause the IR team to run into legal and regulatory hurdles due to limitations placed on what data can be accessed and used in investigations.

Virtualization

Virtualization brings with it all the security concerns of the guest operating system, along with new virtualization-specific threats. A cloud service provider and customers would need to address virtual device hardening, hypervisor security, intervirtual device attacks, performance concerns, encryption, data commingling, data destruction, virtual device image tampering, and in-motion virtual devices.

External Accreditations

Rather than have a cloud service provider respond to numerous contract requests to ensure that all risks are covered, providers can obtain a number of external accreditations that will present evidence that they have both implemented appropriate security controls and follow sound security practices. One of these is the Statement on Auditing Standards (SAS) number 70, commonly known as an SAS 70 audit, which was originally published by the American Institute of Certified Public Accountants (AICPA). The audit is for service organizations and is designed to ensure that the company has sufficient controls and defenses when it is hosting or processing data belonging to one of its customers. A company that has a SAS 70 certificate has been audited by an external auditor, and the control objectives and activities have been found to be acceptable per SAS 70 requirements. When considering cloud providers, customers should look for not only SAS 70, but SAS 70 Type II. Type I certification only states that policies and procedures exist, although there is no audit to ensure that the organization adheres to these procedures. Type II certification comes only after a lengthy and rigorous in-person audit that ensures the service provider adheres to their procedures. Cloud providers, such as Terremark, Rackspace, and Amazon, are SAS 70 Type II certified.

Determining When Security Goals Require a Private Cloud

While the low cost and elastic nature of cloud computing can be beneficial for customers, due to security concerns the deployment method needs to be carefully selected. The security concerns that a potential customer needs to pay attention to are as follows:

- *Data protection (network and storage):* Sensitive and personal data, such as medical, human resources, e-mail, and government communications, will traverse the cloud environment. Securing this data in transit and storage will be important from contractual, legal, and regulatory perspectives.
- *Confidentiality:* Business processes and related information that are crucial to a company's survival may be utilized in a cloud environment. Any leakage of that information caused by voluntary communication by the cloud service provider or the cloud environment's security breach may jeopardize the customer's business and services.
- *Intellectual property:* It is important to determine who will own the intellectual property rights deployed in a cloud environment prior to engaging in cloud

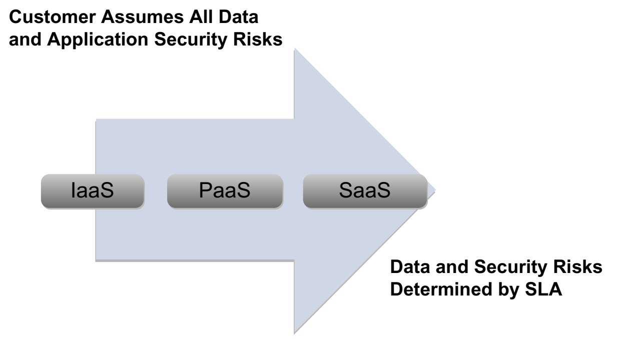

FIGURE 6.2 Risk assumption in cloud service models.

computing activities, and further determine the use that the parties can make of the objects of such rights.

- *Professional negligence:* The customer may be exposed to contractual and tortuous liability to its customers based on negligence due to functions outsourced to the cloud service provider.
- *Outsourcing services and changes in operational control:* A customer may select working with a cloud service provider due to its perceived qualities. If the cloud service provider decides to outsource these services, security concerns could arise owing to the lack of information regarding the processes and their qualities that are adopted by the third parties.

A private cloud deployment model would address all of these concerns by providing an environment owned and managed by the customer or trusted third party, located on-premise or at a trusted location and accessible only by trusted resources. Certain government entities and financial institutions prefer private cloud deployments because of the level of control and physical separation they provide. The progression of risk assumption in cloud service models is shown in Figure 6.2.

2. SOFTWARE AS A SERVICE (SAAS): MANAGING RISKS IN THE CLOUD

In SaaS environments the service levels, privacy, compliance, security controls, and their scope are negotiated into the contracts for service. Therefore, a SaaS customer has the least tactical responsibility compared to the other cloud service models for implementing and managing security solutions.

Centralizing Information with SaaS to Increase Data Security

SaaS storage is always accessed via a Web-based user interface or a client/server application. Data is entered into the system via the Web interface and stored within the SaaS application. SaaS may consume database systems, object and file storage, or dedicated IaaS storage volumes. Data is tagged and encrypted in the SaaS application and generally managed by the provider if natively supported. Data passes through an encryption proxy before being sent to the SaaS application. This proxy can be implemented by the customer or the cloud service provider. This single point of exit and entry provides the means to easily monitor and control data being processed. Since data will be residing in a heterogeneous environment, the provider will need to encrypt data at a customer level and use separate database instances.

Implementing and Managing User Authentication and Authorization

In a SaaS environment, authentication and authorization is managed with a federated ID management solution (also known as a single sign on (SSO)). Federation is the use of Security Assertion Markup Language (SAML) to offer portability to disparate and independent security domains, with some organizations extending their DS (Directory Service) environment via a gateway product that will handle SAML assertions. Other organizations will consume native SAML assertions from an identity service. The following steps will be taken in a simplified SSO approach:

1. The user attempts to access the SaaS provider and will need to do so with some form of identifying information. For example, in the event the SaaS platform is Web based, the identifying information may be in the form of encrypted data in the URL or a cookie.
2. That information will be authenticated against the customer's user directory via a direct Web service call.
3. The customer's user directory will then reply with an assertion containing authorization and authentication information.
4. The resulting request is either fulfilled or denied based on the authentication and authorization of the assertion.

Permission and Password Protection

In a SaaS environment, the provider will offer a comprehensive password protection and permissions system. Password granting and password management (including read, write, delete options) should be clear and straightforward. Passwords will be required to change periodically to random values and will be stored in an encrypted and replicated manner.

Permissions will be assignable at different levels (workgroup, folder, subfolder), depending on the data the employee needs to access, and requestor's permissions

will be validated with every access request as described in the authorization steps. The SaaS platform will capture event logs to track what data was accessed by whom at a given time.

Negotiating Security Requirements with Vendors

Service levels, security, governance, compliance, and liability expectations of the service and provider are contractually stipulated, managed to, and enforced, when the cloud provider offers a service level agreement (SLA) to the consumer. There are two types of SLAs: negotiable and nonnegotiable. When a nonnegotiable SLA is offered, the provider administers those portions stipulated in the agreement. An SLA generally comprises the parties involved, dates, scope of agreement, service hours, security, availability, reliability, support, performance metrics, and penalties.

Identifying Needed Security Measures

The security risks that were previously mentioned need to be identified and addressed by the consumer and stipulated in the SLA. Security departments should be engaged during the establishment of SLAs and contractual obligations to ensure that security requirements are contractually enforceable. SaaS providers that generate extensive customer-specific application logs and provide secure storage as well as analysis facilities will ease the burden on the customer. SLAs should cover data protection, business continuity and recovery, incident response, e-discovery, data retention, and removal [3].

Establishing a Service Level Agreement

Since multiple organizations are involved, SLAs and contracts between the parties become the primary means of communicating and enforcing expectations for responsibilities. It is important to note that the SLAs must be such that the cloud provider informs customers in a timely and reliable manner to allow for agreed actions to be taken. The customer should make sure that SLA clauses are not in conflict with promises made by other clauses or clauses from other providers [3].

SLAs may carry too much business risk for a provider, given the actual risk of technical failures. From the customer's point of view, SLAs may contain clauses that turn out to be detrimental; for example, in the area of intellectual property, an SLA might specify that the cloud provider has the rights to any content stored on the cloud infrastructure.

Ensuring SLAs Meet Organizational Security Requirements

Contracts should provide for third-party review of SLA metrics and compliance (e.g., by a mutually selected mediator). The need to quantify penalties for various risk scenarios in SLAs and the possible impact of security breaches on reputation motivate more rigorous internal audit and risk assessment procedures than would otherwise exist. The frequent audits imposed on cloud providers tend to expose risks that would not otherwise have been discovered, having therefore the same positive effect.

3. PLATFORM AS A SERVICE (PAAS): SECURING THE PLATFORM

A customer's administrator has limited control and accountability in a PaaS environment. With PaaS, securing the platform falls onto the provider, but both securing the applications developed against the platform and developing them securely belong to the customer. Customers need to trust the provider to offer sufficient control, while realizing that they will need to adjust their expectations for the amount of control that is reasonable within PaaS.

PaaS should provide functionality to allow customers to implement intrusion or anomaly detection and should permit the customers to send select events or alerts to the cloud provider's security monitoring platform. PaaS should provide encryption in the application, between client and application, in the database and proxies, as well as any application programming interface (API) that deals with the hosted data. PaaS providers generally permit their customers to perform vulnerability assessments and penetration tests on their systems.

Restricting Network Access Through Security Groups

Segregation through security groups is illustrated in Figure 6.3.

By isolating the network into physically separate parts, the cloud provider can limit traffic between public subnets and infrastructure control subnets. The network can be isolated up to a degree by utilizing network virtualization, but this can suffer from vulnerabilities and misconfiguration. Physical separation is also open to error, but this problem can be minimized by the use of process controls. Network isolation can be achieved by having physically separate networks for administrative and operational traffic, for security and network operations traffic, for storage networks, and for publicly accessible components.

Firewalls are traditionally used for network separation, and when used together with network controls, a firewall can become an extra supporting layer. This is particularly

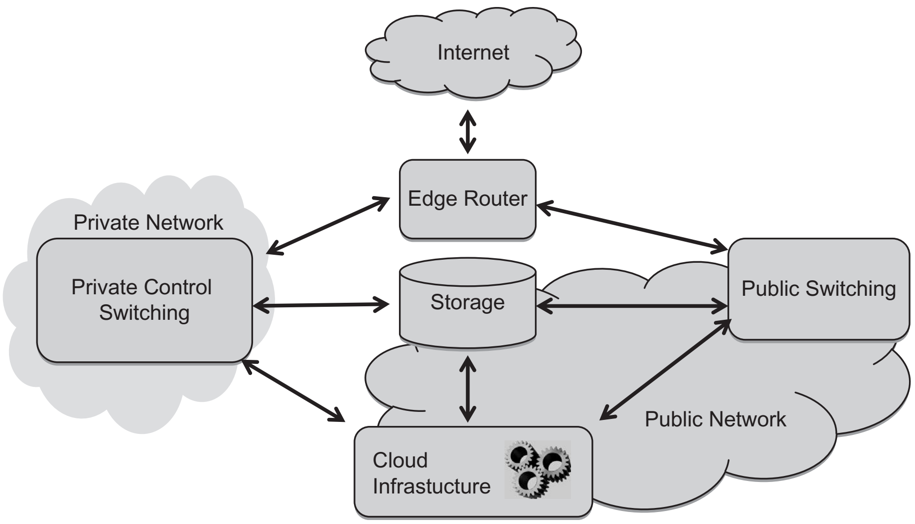

FIGURE 6.3 Segregation through security groups.

helpful when multiple subnets profit from a shared service, such as a directory.

In a PaaS environment, security groups (SGs) can act as a firewall, allowing the customer to choose which protocols and ports are open to computers over the Internet. In Amazon EC2, a security group is a set of ACCEPT firewall rules for *incoming* transmission control protocol (TCP), user datagram protocol (UDP), or internet control message protocol (ICMP). When an instance is launched with a given SG, firewall rules from this group are activated for this instance in EC2's internal distributed firewall [4].

Configuring Platform-Specific User Access Control

The cloud service provider is responsible for handling access to the network, servers, and application platforms in the PaaS model. On the other hand, the customer is responsible for access control of the applications they deploy. Application access control includes user access management, such as user provisioning and authentication. Amazon identity and access management let customers define users and their access levels, entity roles, and permissions, and provides access to federated users within the customer's existing enterprise systems. An example of user access control in PaaS is shown in Figure 6.4.

Integrating with Cloud Authentication and Authorization Systems

User access control support is not uniform across cloud providers, and offered features may differ. A PaaS provider may provide a standard API like OAuth (an open standard for authorization) to manage authentication and access control to applications. Google supports a hybrid

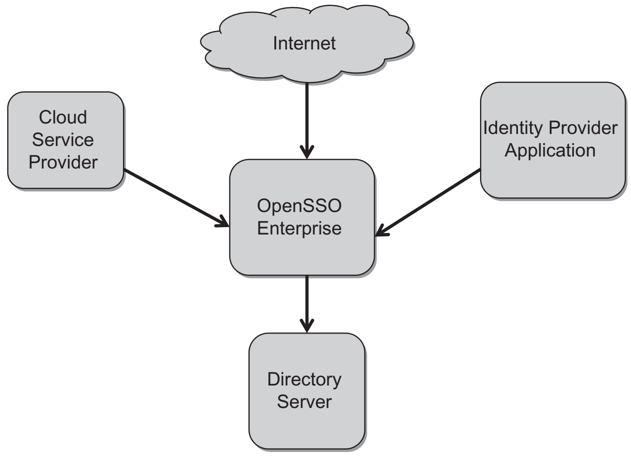

FIGURE 6.4 User access control in PaaS.

version of an OpenID (an open, decentralized standard for user authentication and access control) and OAuth protocol that combines the authorization and authentication flow in fewer steps to enhance usability. The customer could also delegate authentication to the customer's identity provider if the cloud provider supports federation standards, such as SAML. Microsoft announced the "Geneva" Claims-Based Access Platform that is compliant with SAML 2.0 standards. The platform's objective is to help developers delegate authentication, authorization, and personalization so that they don't have to implement these futures themselves.

Compartmentalizing Access to Protect Data Confidentiality

When data is stored with a PaaS provider, the provider assumes partial responsibility as the data custodian.

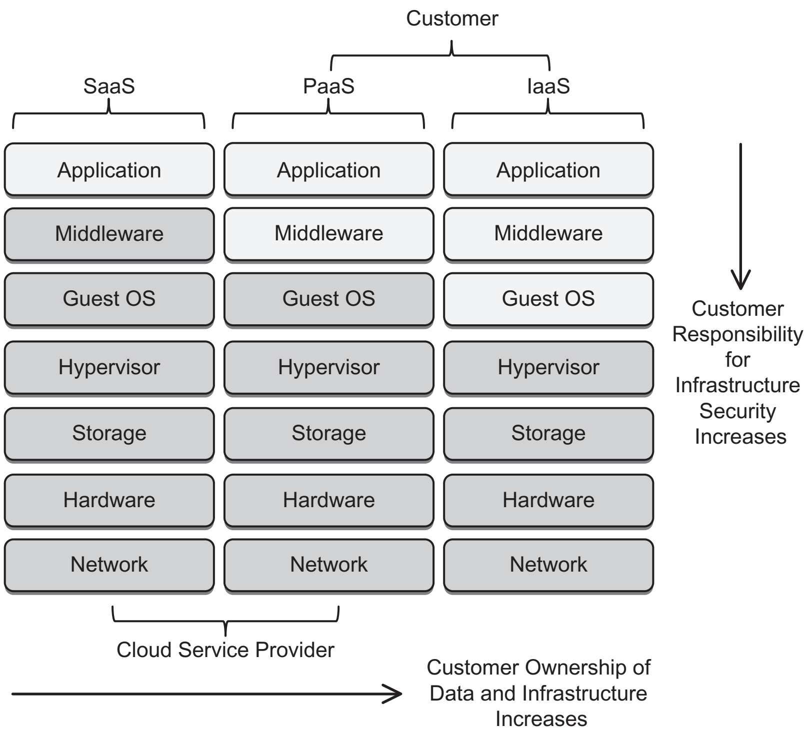

FIGURE 6.5 Ownership in different service models.

Although the responsibilities for data ownership and data custodianship are segregated, the data owner is still accountable for ensuring that data is suitably safeguarded by the custodian, as seen in Figure 6.5. In a PaaS environment, compartmentalizing access provides data confidentiality since users are prevented from being able to access certain information because they do not need access to it to perform their job functions and they have not been given formal approval to access this data (least privilege design).

Securing Data in Motion and Data at Rest

Data at rest denotes data stored in computer systems, including files on an employee's laptop, company files on a server, or copies of these files on an off-site tape backup. Securing data at rest in a cloud is not drastically different than securing it outside a cloud environment. A customer deploying in a PaaS environment needs to find the risk level acceptable and to make sure that the cloud provider is the primary custodian of the data.

Data in motion indicates data that is transitioning from storage, such as a file or database entry, to another storage format in the same or to a different system. Data in motion can also include data that is not permanently stored. Because data in motion only exists in transition (e.g., computer memory, between end points), its integrity and confidentiality must be ensured. The risk of third party observation of the data in motion exists. Data may be cached on intermediate systems, or temporary files may be created at either endpoint. The best method to protect data in in motion is to apply encryption.

Identifying Your Security Perimeter

With the acceptance of cloud services, an organization's security perimeter has evolved to become more dynamic and has moved beyond the control of the traditional IT department. Cloud computing has extended an organization's network, system, and application realms into the cloud service provider's domain.

The Jericho Forum, an open-group consortium of IT security officers, has addressed deperimeterization. In the view of the Jericho Forum, it is essential to pinpoint the components that are critical to the customer's operation and to ensure that those are sufficiently secured, regardless of the source of the threat. In a completely deperimeterized environment, every component will be sufficiently secured to ensure that confidentiality, integrity, and availability of the data are maintained.

Techniques for Recovering Critical Data

A PaaS customer should review the available options for backup and recovery of their critical data and understand the different options available to secure the data transfer in case of an emergency. The customer should also ensure that backups and other copies of logs, access records, and

any other pertinent information that may be required for legal and compliance reasons can be migrated. Data validation should be an automated or user-initiated validation protocol that allows the customer to check its data at any time to ensure the data's integrity. The cloud provider should implement fast SLA-based data recovery. The SLA should be negotiated upfront, and the customer should pay for the SLA required to ensure that there is no conflict of interest. No data, no file, or no system disk, should take more than 30 minutes to recover. PaaS providers can offer one or more of the following options:

- Basic backup and restore
- Pilot light
- Warm standby
- Multisite

Basic Backup and Restore

PaaS providers can offer storage space on their own platform where the transfer of data is performed over the network. The storage service enables snapshots of the data to be transparently copied into the storage systems. Some providers permit the transfer of large data sets by shipping the storage devices directly.

Pilot Light

The notion of the pilot light is an analogy that originates from the gas heater. In a gas heater, a small flame that is always burning can rapidly kindle the entire heater to warm up a house when desired. This situation is comparable to a backup and restore scenario; nevertheless, the customer must make sure that the critical core components of the system are already configured and running in a PaaS environment (the pilot light). When it's time for recovery, the customer would quickly provision a full-scale production environment based on the critical core components. The pilot light method will provide the customer with a shorter recovery time than the backup and restore option, because the core components of the system already exist, are running, and are continuously updated. There remains some installation and configuration tasks that need to be performed by the customer to fully recover the applications. The PaaS environment allows customers to automate the provisioning and configuration of the resources, which can save time and minimize human errors.

Warm Standby

The warm standby option extends the pilot light components and preparation. The recovery time decreases further because some services are always operating. After identifying the business-critical components, the customer would duplicate these systems in the PaaS environment and configure them to be always running. This solution is not configured to handle a maximum production load, but it provides all of the available functions. This option may be utilized for testing, quality assurance, and internal use. In case of a catastrophe, additional resources are rapidly added to handle the production load.

Multisite

The multisite option exists in the PaaS environment as well as on the customer's on-site infrastructure where both are running. The recovery point selected will determine the data replication method that the customer employs. Various replication methods exist, such as synchronous or asynchronous. A Domain Naming Service (DNS) load balancing service can be used to direct production traffic to the backup and production sites. Part of the traffic will go to the infrastructure in PaaS, and the rest will go to the on-site infrastructure. In case of a catastrophe, the customer can adjust the DNS configuration and send all traffic to the PaaS environment. The capacity of the PaaS service can be rapidly increased to handle the full production load. PaaS resource bursting can be used to automate this process if available from the provider. The customer may need to deploy application logic to detect the failure of the primary site and divert the traffic to the parallel site running in PaaS. The cost of this option is determined by resource consumption.

4. INFRASTRUCTURE AS A SERVICE (IAAS)

Unlike PaaS and SaaS, IaaS customers are primarily responsible for securing the hosts provisioned in the cloud.

Locking Down Cloud Servers

Unlike PaaS and SaaS, IaaS customers are accountable for securing the systems provisioned in the cloud environment. Knowing that most IaaS services available today implement virtualization at the host level, host security in IaaS could be classified as follows.

Virtualization Software Security

Virtualization software is the software that exists on top of hardware and provides customers the capability to create and delete virtual instances. Virtualization at the host level can be achieved by utilizing virtualization models, such as paravirtualization (specialized host-operating system, hardware and hypervisor), operating system-level virtualization (FreeBSD jails, Solaris Containers, Linux-VServer), or hardware-based virtualization (VMware, Xen). In a public IaaS environment, customers cannot access the hypervisor because it is

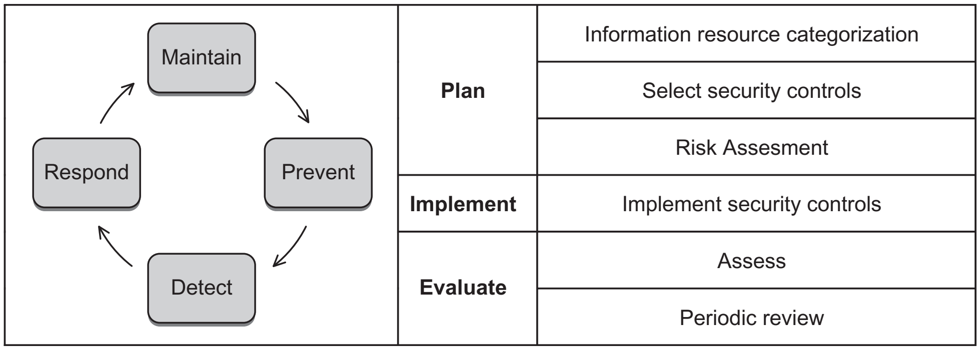

FIGURE 6.6 Cloud computing key best practices.

administered solely by the cloud services provider. Cloud services providers should implement the essential security controls, including limiting physical and logical access to the hypervisor and the other virtualization layers. IaaS customers need to comprehend the technology and access controls implemented by the cloud services provider to guard the hypervisor. This will aid the customer to recognize the compliance needs and gaps in relation to the host security standards, policies, and regulations. To show the weakness of the virtualization layer, during Black Hat 2008 and Black Hat DC 2009 Joanna Rutkowska, Alexander Tereshkin, and Rafal Wojtczuk from Invisible Things Lab showed various methods to compromise the Xen hypervisor's virtualization, including the "Blue Pill" attack.

Customer Guest Operating System (OS) or Virtual Instance Security

The virtual incarnation of an operating system is created over the virtualization layer, and it is usually configured to be exposed to the Internet. Customers have complete access to their virtual machines. Public IaaS systems can be exposed to security threats, such as the theft of keys used to access hosts (e.g., SSH private keys), the attack of exposed vulnerable services (e.g., FTP, NetBIOS, SSH), the hijacking of insecure accounts (i.e., weak or no passwords), and the deployment of malware as software or embedded in the operating system.

Ensuring the Cloud is Configured According to Best Practices

Cloud computing is still subject to conventional security best practices, but cloud services providers and their customers may find it difficult to adopt these practices since they are not tailored to the cloud space. The security best practices for cloud computing has been maturing rapidly through the contribution of the players involved in cloud computing, such as hardware manufacturers, software providers, cloud providers, and customers. The key best practices are as follows and can be seen in Figure 6.6:

- Policy
- Risk management
- Configuration management and change control
- Auditing
- Vulnerability scanning
- Segregation of duties
- Security monitoring

Policy

It is a best practice for cloud services providers and their customers to define a solid policy for cloud security. This policy should include all security-related aspects of information security, including staff, information, infrastructure, hardware, and software. Policies are crucial to provide organizational direction. To succeed, they must be available and visible across the organization, they must have the backing of management, and they must assign responsibilities. Policies should be updated continuously, and they should be accompanied by the use of standards, procedures, and guidelines that enable the implementation of policy.

Risk Management

The goals of risk management best practices are to assess, address, and mitigate security risks in a cloud environment. This should be done in the context of determining the risks from a business standpoint. Choosing security controls and monitoring their efficacy are part of risk management. Basically, a best practice for risk management is to begin with an understanding and assessment of the risks one faces (risk analysis) and orient the selection of security controls along with appropriate security practices and procedures toward managing risks.

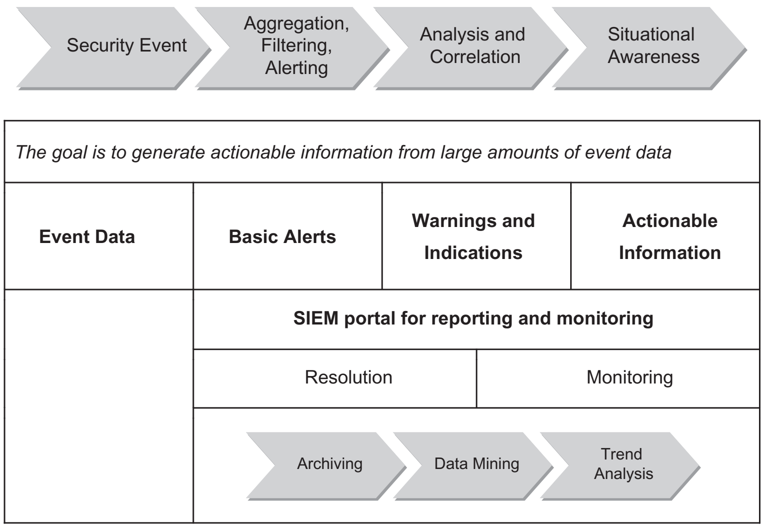

FIGURE 6.7 Security monitoring life cycle.

Configuration Management and Change Control

It is a best practice to have a configuration and change management process that can govern proposed changes. This would also include identifying possible security consequences, and providing assurance that the current operational system is correct in version and configuration.

Auditing

In auditing, the customer should seek to verify compliance, review the efficacy of controls, and validate security processes. The customer should follow a schedule in auditing, regularly evaluate security controls, use automated and manual processes to validate compliance to a policy, regularly use third-party vulnerability assessment services, and manually examine system logs to validate the effectiveness of the security monitoring systems.

Vulnerability Scanning

It is a best practice to perform periodic cloud infrastructure vulnerability scanning. This should encompass all cloud management systems, servers, and network devices. The purpose of vulnerability scanning is to locate any new or existing vulnerability so that the related risk may be reduced or eliminated.

Segregation of Duties

It is a best practice to limit the user's privileges to the level necessary for them to perform their duties. This comes from the idea of separation of duties, which in turn originates from the principle of least privilege.

Security Monitoring

It is a best practice to automate the collection of security logs from all network devices, servers, and applications. These logs should be kept in their original formats in order to preserve a legal record of all activity and so that they can be queried in an event of an alert. The purposes of security monitoring are to detect threats, expose bugs, keep a legal record of activity, and enable forensics. The most likely sources of security events are operating system logs (event logs and syslogs), application logs, intrusion detection and prevention logs, anti-virus logs, netflow logs, network device logs, and storage equipment logs. These security events are aggregated in streams and redirected via the network to a central collection service, usually a Security Information and Event Management (SIEM) system. Once these events are collected, they should be subject to an ongoing correlation and analysis process, usually performed by a Security Operation Center (SOC). The events get escalated as they are evaluated and assigned alert levels and priorities. The security monitoring life cycle is shown in Figure 6.7.

Confirming Safeguards have been Implemented

Once the IaaS environment has been implemented, it should undergo a continuous evaluation in the form of change management and periodic evaluation in the form of control review. The outcome of these evaluations would be to remedy the issues and to continue the evaluation the process. The following can be used as a generalized checklist to evaluate the IaaS environment:

- Foundations of Security
  - Policies, standards, and guidelines

  - Transparency
  - Employee security
  - External providers
- Business Concerns
  - Business continuity
  - Disaster recovery
  - Legal considerations
  - Resource planning
- Layers of Defense
  - Software assurance
  - Authentication
  - Key management
  - Cryptography
  - Network security
  - Hypervisor and virtual machine security
  - Identity and access management
- Operational Security
  - Operational practices
  - Incident response management
  - Data center: Physical security, power and networking, asset management

Networking

The primary factor in determining whether to use private, public, or hybrid cloud deployments is the risk level an organization can tolerate. Although various IaaS providers implement virtual network zoning, they may not be the same as an internal private cloud that employs stateful inspection and other network security services. If customers have the budget to afford the services of a private cloud, their risks will decline, given they have a private cloud that is internal to their network. In some instances, a private cloud located at a cloud provider's facility can help satisfy security requirements, but will be dependent on the provider's capabilities and maturity. Confidentiality risk can be reduced by using encryption for data in transit. Secure digital signatures can make it more difficult for malicious players to tamper with data and therefore, ensure the integrity of data. The cloud service provider should provide the following information to the customer:

- Data and access control threats
- Access and authentication controls
- Information about security gateways (firewalls, Web application firewalls, service-oriented architecture, and application programming interface)
- Secure services like DNSSEC, NTP, OAuth, SNMP, and management network segmentation
- Traffic and network flow monitoring capabilities
- Hypervisor integration availability
- Security products (IDS/IPS, Server Tier Firewall, File Integrity Monitoring, DLP, Anti-Virus, Anti-Spam)
- Security monitoring and incident response capabilities
- Denial-of-service (DoS) protection and mitigation capabilities

Operating Systems

The ease of self-provisioning new virtual instances on an IaaS platform creates a possibility that insecure virtual servers may be created. Secure-by-default configuration should be implemented by default by mirroring or surpassing industry best practices. Securing a virtual instance in the cloud requires solid operational security procedures supported by automation of procedures. The following steps can be used to evaluate host and virtual machine (VM) security:

- Use a hardened system configuration. A best practice for cloud applications is to build hardened virtual machine images that have only the configuration sufficient to support the application stack. Limiting the abilities of the basic application stack not only limits the server's attack surface, but also greatly decreases the number of updates needed to maintain a secure application stack.
- Keep track of the available virtual machine images and operating system versions that are offered for cloud hosting. The IaaS provider offers some of these VM images through their infrastructure. If a virtual machine image from the IaaS provider is utilized, it should go through the same security verification and hardening process for systems within the enterprise infrastructure. The best substitute for the customer is to build its image that matches the security standards of the internal trusted systems.
- Maintain the integrity of the hardened image.
- Secure the private keys required to access hosts in the cloud.
- Separate the cryptographic keys from the cloud where the data is hosted. The exception to this would be when the keys are necessary for decryption, and this would be limited to the duration of the decryption activity. If the application needs a key to continuously encrypt and decrypt, it may not be feasible to protect the key since it will be hosted with the application.
- Do not place credentials in the virtual machine images except for a key to decrypt the file system.
- Do not permit password-based authentication for remote access.
- Require passwords to execute administrative functions.
- Install a host firewall and open to the public only the minimum ports necessary to support the services.
- Run only the needed services, and turn off the unused services (e.g., turn off FTP, print services, network

file services, and database services if they are not required).
- Install a host-based intrusion detection system (IDS).
- Log system and event logs to a dedicated log aggregator. Isolate the log server with strong access controls.
- Ensure a system to provide patching images in the cloud; both online and offline is available.
- Ensure that isolation between different customers (network and data) is provided.

Applications

The integrity and security of a cloud environment is dependent on the integrity of its components. Software is a primary route for vulnerabilities and exploits. IaaS providers, such as Amazon EC2 and Terremark, handle the applications on customer virtual machines as black boxes. This makes the providers completely independent of the operations and management of the customer's applications. Therefore, customers bear the full responsibility for securing their applications deployed in the cloud.

Web applications installed on a public cloud should be designed with an Internet facing threat model and protected with typical security measures against Web application vulnerabilities, such as those listed in the the Open Web Application Security Project (OWASP) Top 10 Web application security risks. Following common security development practices, they should also be periodically audited for vulnerabilities. Security should be embedded into the software development life cycle. It's the customers' responsibility to keep their applications and runtime platform up to date to protect their systems from a compromise. It is in the customer's best interest to designs and implement applications with the least-privileged access model.

Developers creating applications for IaaS clouds should develop their own mechanisms for authentication and authorization. Similar to traditional identity management implementations, cloud applications should also be designed to use delegated authentication services offered by an enterprise identity provider. If in-house implementations of authentication, authorization, and accounting are not properly designed, they can become a weakness. Cloud customers should avoid using in-house authentication, authorization, and accounting solutions when possible.

Scanning for and Patching Vulnerabilities

Penetration testing and vulnerability assessments of cloud infrastructure should be carried out on a periodic basis. Usually, the customer may not have the specialized skills and expertise to perform these tests; therefore, the customer should work with a third party that is professional and has the necessary skills and certifications. Penetration testing should be geared toward the entire cloud infrastructure and not just individual components. Security is only as good as the weakest link.

A penetration test and vulnerability assessment can uncover multiple vulnerabilities, not all of which can or should be fixed. Newly found vulnerabilities need to be classified by their severity. Generally, a vulnerability that is categorized as critical should be addressed to safeguard the entire cloud. Vulnerabilities categorized as having low and medium severity may be accepted as reasonable risks. Vulnerabilities that are not addressed need to have their residual risk evaluated and then accepted by the customer. If it is found that the same vulnerability exists across all servers with the virtual machine image, then this should be fixed in the golden virtual machine image.

Vulnerability scanning has additional benefits. If one collects scan data against the same targets and stores the scan results in a database, configuration errors and attack trends can be detected by analysis of this data over time. Likewise, use of a database to store scanning results, makes these immediately available to auditors and automated tools for compliance and other security checking.

Controlling and Verifying Configuration Management

The relationship between configuration management and security control procedures is an often-neglected one in commercial implementations of Internet-facing systems. The root cause is typically a process failure in configuration management or change control (CC). A recognition of this problem is found in NIST SP 800−64, Security Considerations in the Information System Development Life Cycle, which states: "Changes to the hardware, software, or firmware of a system can have a significant impact on the security of the system . . . changes should be documented, and their potential impact on security should be assessed regularly." Configuration management and change management should be well defined and provide a structured method for causing technical and administrative changes. They should also provide assurances that the information technology resources in operation are correct in their version and configuration. Configuration management and change management are essential to controlling and managing an accurate inventory of components and changes.

Vulnerability assessments can be used to confirm the configuration management data. When issues that have not been previously identified are discovered, more thorough investigation becomes necessary.

Most of the time cloud providers are responsible for the vulnerability, patch, and configuration administration

of the infrastructure (hosts, storage, networks, and applications). Cloud providers should assure their customers of their technical vulnerability management program using ISO/IEC 27002 type control and assurance frameworks.

IaaS configuration management and change control focuses on infrastructure managed by the cloud provider, as well as the customer infrastructure interfacing with the IaaS environment. Therefore, the provider should be responsible for systems, networks, hypervisors, employee systems, and storage and management applications owned and operated by the provider and third parties. Instead, IaaS customers are responsible for their virtual servers, image standardization, configuration standardization, configuration management of the customer environment, and network access policies.

5. LEVERAGING PROVIDER-SPECIFIC SECURITY OPTIONS

Due to the elastic model of services delivered via the cloud, customers need only pay for the amount of security they require, such as the number of workstations to be protected or the amount of network traffic monitored, and not for the supporting infrastructure and staffing to support the various security services. A security-focused provider offers greater security expertise than is typically available within an organization. Finally, outsourcing administrative tasks, such as log management, can save time and money, allowing an organization to devote more resources to its core competencies. The security options that are provided by various cloud providers are as follows:

- Network security
- Multifactor authentication
- Identity and access management
- Data loss prevention
- Encryption
- Business continuity and disaster recovery
- Web security
- Email security
- Security assessments
- Intrusion management, detection, and prevention
- Security information and event management

Defining Security Groups to Control Access

The conventional model of network zones and tiers has been supplanted in public clouds with security groups, security domains, or virtual data centers that have logical boundaries between tiers but are less exact and offer less protection than the earlier model. A security group acts as a firewall that controls the traffic allowed into a group of instances. When the customer launches a virtual instance, it can assign the instance to one or more security groups. For each security group, the customer adds rules that govern the allowed inbound traffic to instances in the group. All other inbound traffic is discarded. The customer can modify rules for a security group at any time. The new rules are automatically enforced for all existing and future instances in the group. The default security group usually allows no inbound traffic and permits all outbound traffic. A virtual instance can have as many security groups as needed.

Filtering Traffic by Port Number

Each security group rule enables a specific source to access the instances in the group using a certain protocol (TCP, UDP, ICMP) and destination port or ports. For example, a rule could allow a source IP address 1.1.1.1 to access the instances in the group on TCP port 80 (the protocol and destination port).

Discovering and Benefiting from the Provider's Built-in Security

Some IaaS providers have the mentioned security options built into their systems. Amazon EC2 provides its customers with identity and access management (IAM) policies and security groups (SGs). Other providers such as Terremark have multifactor authentication built into their Enterprise Cloud solutions besides IAM and SG. These built-in features decrease the time needed to launch a secure environment and reduce the cost further.

Protecting Archived Data

The same three information security principles are associated with data stored in the cloud as with data stored elsewhere: confidentiality, integrity, and availability.

Confidentiality

Confidentiality is usually provided by encrypting customer data. Data can be at the volume storage level or object storage level.

Volume storage encryption prevents snapshot cloning or exposure, exploration by the cloud provider, and exposure due to physical loss of drives. IaaS volumes can be encrypted using instance-managed encryption (instance managed, keys stored in volume and protected by a secret or key pair), externally managed encryption (instance managed, keys are managed externally, provided on request), or proxy encryption (external software or appliance managed).

Object or file storage encryption allows the user to implement virtual private storage (VPS). Like a virtual

private network, VPS allows the use of a public shared infrastructure while still protecting data, since only those with encryption keys can read the data. The objects can be encrypted by standard tools, by the application using the data, or by a proxy before being placed in storage.

IaaS providers can also offer IAM policies and access control lists (ACLs) to further protect stored data. The transfer of data is also protected by provider-implemented SSL or VPN connections.

Integrity

Besides the confidentiality of data, the customer also needs to consider the integrity of their data. Confidentiality does not mean integrity. Data can be encrypted for confidentiality reasons, but the customer might not have a method to validate the integrity of that data. IaaS providers should regularly check for integrity by keeping track of data checksums and repair data if corruptions are detected by using redundant data. Data in transfer should also be checksum validated to detect corruption.

Availability

Supposing that customers' data has preserved its confidentiality and integrity, the customers should also be worried about the availability of their data. They should be concerned about three main threats: network-based attacks; the cloud service provider's own availability; and backups or redundancy. Availability is usually stated in the SLA, and customers pay for varying levels of availability based on their risk tolerances. IaaS providers may provide redundant storage (geographic and systemic), versioning, and high-bandwidth connectivity to prevent problems arising from availability issues.

6. ACHIEVING SECURITY IN A PRIVATE CLOUD

In private clouds, computing and storage infrastructure are dedicated to a single organization and are not shared with any other organization. However, just because they are private does not mean that they are more secure.

Taking Full Responsibility for Security

The security management and day-to-day operation of the environment are relegated to internal IT or to a third party with contractual SLAs. The risks faced by internal IT departments still remain. Private cloud security should be considered from different perspectives:

- *Infrastructure security:* This perspective includes physical access and data leakage concerns (loss of hard drives), energy supply security, facility security, network security, hardware security (hardware cryptography modules, trusted protection modules), compute security (process, memory isolation), storage security, operation system security, virtualization security, and update security (hypervisor, virtual machines).
- *Platform security:* This perspective includes user experience security, application framework security, data security, development environment security, and update security.
- *Software security:* This perspective includes application security (multi-tenant partitioning, and user permissions) and update security.
- *Service delivery security:* This perspective includes connection security (SSL, authentication), and service endpoint security (traditional network security).
- *User security:* This perspective includes making sure that the users and the systems they are using to access the private cloud are trusted and secured.
- *Legal concerns:* This perspective includes governance issues, compliance issues (PCI DSS, HIPPA), data protection (personally identifiable information), and legal agreements (SLA, terms of use, user license agreements).

The advantages of a private cloud in the context of security become apparent mostly when compared to a public cloud implementation.

Managing the Risks of Public Clouds

Although a public cloud deployment is suitable for most uses that are nonsensitive, migrating sensitive, mission-critical, or proprietary data into any cloud environment that is not certified and designed for handling such data introduces high risk. A customer should first select a cloud deployment model and then make sure that sufficient security controls are in place. These actions should be followed by a reasonable risk assessment:

- *Data and encryption*: If the data is stored unencrypted in the cloud, data privacy is at risk. There is the risk for unauthorized access either by a malicious employee on the cloud service provider side or an intruder gaining access to the infrastructure from the outside.
- *Data retention*: When the data is migrated or removed by the cloud provider or customer, there may be data residues that might expose sensitive data to unauthorized parties.
- *Compliance requirements*: Various countries have varying regulations for data privacy. Because some public cloud providers don't offer information about the location of the data, it is crucial to consider the

legal and regulatory requirements about where data can be stored.

- *Multi-tenancy risks*: The shared nature of public cloud environments increases security risks, such as unauthorized viewing of data by other customers using the same hardware platform. A shared environment also presents resource competition problems whenever one of the customers uses most of the resources due either to need or to being exposed to targeted attacks, such as DDoS (distributed denial of service).
- *Control and visibility*: Customers have restricted control and visibility over the cloud resources because the cloud provider is responsible for administering the infrastructure. This introduces additional security concerns that originate from the lack of transparency. Customers need to rethink the way they operate as they surrender the control of their IT infrastructure to an external party while utilizing public cloud services.
- *Security responsibility*: In a cloud the vendor and the user share responsibility forsecuring the environment. The amount of responsibility shouldered by each party can change depending on the cloud model adopted.

Identifying and Assigning Security Tasks in Each SPI Service Model: SaaS, PaaS, IaaS

Security-related tasks tend to be the highest for the cloud provider in an SaaS environment, whereas an IaaS environment shifts most of the tasks to the customer.

- SaaS
  - *Attack types:* Elevation of privilege, cross-site scripting attack (XSS), cross-site request forgery (CSRF), SQL injection, encryption, open redirect, buffer overflows, connection polling, canonicalization attacks, brute force attacks, dictionary attacks, token stealing.
  - *Provider security responsibilities:* Identity and access management, data protection, security monitoring, security management, authentication, authorization, role-based access control, auditing, intrusion detection, incident response, forensics.
  - *Consumer security responsibilities:* Other than assessing the risk of being in a cloud environment, the customer has little to do in SaaS environment.
- PaaS
  - *Attack types:* Data tampering, buffer overflows, canonicalization attacks, Structured Query Language (SQL) injection, encryption, disclosure of confidential data, elevation of privilege, side-channel attacks (VM-to-VM)
  - *Provider security responsibilities:* Security monitoring, security management, authentication, authorization, role-based access control, auditing, intrusion detection, incident response, forensics
  - *Customer security responsibilities:* Identity and access management, data protection
- IaaS
  - *Attack types:* Data tampering, side-channel attacks (VM-to-VM , VM-to-host or host-to-VM), encryption, network traffic sniffing, physical access, brute force attacks, dictionary attacks
  - *Provider security responsibilities:* Role-based access control, auditing, intrusion detection, incident response, forensics
  - *Customer security responsibilities:* Identity and access management, data protection, security monitoring, security management, authentication, authorization

Selecting the Appropriate Product

While evaluating cloud computing products, customers usually want to know about how secure the implementation is, if the cloud provider is meeting best practices for security, how well the cloud provider is meeting discrete controls and requirements, and how the product compares with other similar services.

Comparing Product-Specific Security Features

To be able to compare cloud providers, we need to define a set of metrics and standards. Based on the previous discussions of risk and cloud security coverage, we can use the following set:

- *Organizational security:* Staff security, third-party management, SLAs
- *Physical security:* Physical access controls; access to secure areas, environmental controls
- *Identity and access management:* Key management, authorization, authentication
- *Encryption:* Connection encryption (SSL, VPN), stored data encryption
- *Asset management and security:* Asset inventory, classification, destruction of used media
- *Business continuity (BC) and disaster recovery (DR) management:* Recovery point objective and recovery time objective information, information security during DR and BC, recovery priority, dependencies
- *Incident management:* Existence of a formal process, detection capabilities, real-time security monitoring, escalation procedures, statistics
- *Legal concerns and privacy:* Audits, certifications, location of data, jurisdiction, subcontracting, outsourcing, data processing, privacy, intellectual property

The vendors that provide the highest transparency into their services will have higher coverage of metrics and a possibly higher score than the vendor with less documentation. Some vendors will lack the specific feature or will not document it properly and therefore, will not have a score for the specific metric.

Considering Organizational Implementation Requirements

Besides comparing the cloud provider's products, the customers also need to be well aware of their organization's security requirements and how they align with the cloud provider's offerings. The customers should check for the following organizational requirements to see if they apply:

- Data
  - Separation of sensitive and nonsensitive data: Segregate sensitive data from nonsensitive data into separate databases in separate security groups when hosting an application that handles highly sensitive data.
  - Encryption of non-root file systems: Use only encrypted file systems for block devices and non-root local devices.
  - Encryption of file system key: Pass the file system key encrypted at start-up.
  - Signing of content in storage.
  - Secure handling of decryption keys and forced removal after use: Decryption keys should be in the cloud only for the duration of use.
- Applications
  - No dependence on a specific virtual machine system (operating system or other cloud services).
  - Source address filtering of network traffic: Only allow needed traffic, such as HTTP and HTTPS.
  - Encryption of network traffic.
  - Strong authentication of network-based access: Authentication should preferably be performed using keys by performing mutual authentication.
  - Use of host-based firewall.
  - Installation of a network-based intrusion detection system (NIDS).
  - Installation of a host-based intrusion detection system (HIDS).
  - Usage of hardening tools: Usage of hardening tools, such as Bastille Linux, and SELinux should be possible.
  - System design for patch roll-out: System should be designed to easily patch and relaunch instances.
  - Support of SAML or other identity and access management systems.
- Other
  - Compliance support: Presence of SAS 70 Type II, PCI DSS, and other compliance certifications.
  - Regular full backups stored in remote secure locations.
  - Instance snapshots in case of a security breach.
  - Role segregation: The infrastructure should be segmented based on roles (development, production).
  - Regular verification of cloud resources configuration: This is especially important since cloud resources can be managed via different channels (Web console and APIs). Thus, if, for example, the Web console access has been hacked, this might not be immediately visible to the customer if normally management is only done via APIs. Therefore, some type of intrusion detection for the cloud resource management is needed.
  - No credentials in end-user devices.
  - Secure storage and generation of credentials.
  - Security groups: Security groups (i.e., named set of firewall rules) should be used to configure IP traffic to and from instances completely in order to isolate every tier, even internally to the cloud.

Virtual Private Cloud (VPC)

VPC can offer public cloud users the privacy of a private cloud environment. In a VPC, while the infrastructure remains public, the cloud provider lets the customers define a virtual network by letting them select their own subnets, IP address ranges, route tables, and network gateways. Optionally virtual private networks (VPNs) are provided to further secure the virtual networks. Stored data can also be protected by assigning ACLs.

Simulating a Private Cloud in a Public Environment

VPCs utilize VPNs to secure communication channels by creating protected, virtually dedicated conduits within the cloud provider network. This eradicates the necessity to specify intricate firewall rules between the application in the cloud and the enterprise, because all locations would be linked by a private network isolated from the public Internet. VPNs form the construct of a private network and address space used by all VPN endpoints. Because VPNs can use specific IP addresses, the cloud provider can permit customers to utilize any IP address ranges without conflicting with other cloud customers. A VPC can contain many cloud data centers, but it appears as a single collection of resources to the customer.

Google Secure Data Connector (SDC)

SDC provides data connectivity and allows IT administrators to control the services and data that are available in Google Apps (Web-based office suite). SDC builds a

secure link by encrypting connections between Google Apps and customer networks. Google Apps is the only external service that can make requests over the secured connection. SDC can filter the types of requests that can be routed. The filters can limit which gadgets, spreadsheets, and App Engine applications may access which internal systems. Filters can also be used to limit user access to resources. SDC implements OAuth Signed Fetch that adds authentication information to requests that are made through SDC. The customer can use OAuth to validate requests from Google and provide an additional layer of security to the SDC filters.

Amazon VPC

Amazon VPC lets their customers cut out a private section of their public cloud where they can launch services in a virtual network. Using the Amazon VPC, the customer can delineate a virtual network topology that is similar to a traditional network where the customer can specify its own private IP address range, segregate the IP address range into private and public subnets, administer inbound and outbound access using network access control lists, store data in the Amazon S3 storage service and set access permissions, attach multiple virtual network interfaces, and bridge the VPC with on-site IT infrastructure with a VPN to extend existing security and management policies.

Industry-Standard, VPN-Encrypted Connections

A customer might simply want to extend its organization's perimeter into the external cloud computing environment by using a site-to-site VPN and operating the cloud environment making use of its own directory services to control access. Companies such as Terremark and Rackspace offer site-to-site VPN solutions to extend the existing IT infrastructure into their clouds so that customers can securely use solutions deployed in the cloud (e.g., collaboration solutions, testing and development, data replication, DR).

The Hybrid Cloud Alternative

A hybrid cloud can be created by combining any of the three cloud types: public, private, and virtual private. Hybrid clouds are formed when an organization builds a private cloud and wants to leverage its public and virtual private clouds in conjunction with its private cloud for a particular purpose. An example of a hybrid cloud would be a Web site where its core infrastructure is only accessible by the company, but specific components of the Web site are hosted externally, such as high-bandwidth media (video streaming or image caching). Nevertheless, some requirements can thwart hybrid cloud acceptance. For example, financial services companies, such as banks, might not be able to comply with regulations if customer data is hosted at a third-party site or location, regardless of the security controls. Governments also might not be able to take the risk of being compromised in case of a hybrid cloud breach.

Connecting On-Premises Data with Cloud Applications

Data transferred to the cloud should be encrypted both when on the cloud and during transfer (e.g., with SSL, VPN). The employed encryption service should provide well-thought-out encryption key management policies to guarantee data integrity. Also, the customer should retain encryption key ownership to maintain separation of duties between their business and the other cloud service providers. This permits the customers to use their encryption throughout their private and public clouds and therefore, lets them avoid vendor lock-in and to move between cloud providers.

Securely Bridging with VPC

As the name suggests, a VPC does not deliver a fully private infrastructure, but a virtually private infrastructure. Servers created in the customer's VPC are allocated from the same shared resources that are used by all other provider customers. Hence, the customer still has to consider extra security measures in the cloud, both for networking (interserver traffic) and data in shared storage.

To be able to securely bridge existing infrastructure with VPCs, the customer would need to employ tools such as CloudSwitch or Vyatta. These tools provide data isolation for the data circulating between the in-house data center and the VPCs using data encryption and therefore, applying an additional layer of security. For example, CloudSwitch isolates all network and storage access to data at the device level with AES-256 encryption. It also utilizes roles and permissions-based access to enforce corporate policies.

Dynamically Expanding Capacity to Meet Business Surges

Cloudbursting is the dynamic arrangement of an application operating on a private cloud to use public clouds to meet sudden, unforeseen demand, such as a tax services company's need to meet increasing traffic associated with tax-filing deadlines. The benefit of this type of hybrid cloud usage is that the customer only pays for the additional computing resources when they are in demand. To utilize cloudbursting, a customer would need to address workload migration (ability to clone the application environment with tools such as Chef, Puppet, CFEngine,

Cloudify), data synchronization (maintaining real-time data copies), and network connectivity.

7. MEETING COMPLIANCE REQUIREMENTS

Cloud providers recognize the difficulty of meeting a wide range of customer requirements. To build a model that can scale, the cloud provider needs to have solid set of controls that can benefit all of its customers. To achieve this goal, the cloud provider can use the model of governance, risk, and compliance (GRC). GRC acknowledges that compliance is an ongoing activity requiring a formal written compliance program. The cloud provider should undergo a continuous cycle of risk assessment, identifying the key controls, monitoring, and testing to identify gaps in controls (Security Content Automation Protocol or SCAP, Cybersecurity Information Exchange Framework or CYBEX, GRC-XML), reporting, and improving on the reported issues. The cycle of compliance evaluation is shown in Figure 6.8.

Managing Cloud Governance

Governance is the set of processes, technologies, customs, policies, laws, and institutions affecting the way an enterprise is directed, administered, or controlled. Governance also comprises the relationship betwen the stakeholders and the goals of the company. Governance includes auditing supply chains, board and management structure and process, corporate responsibility and compliance, financial transparency and information disclosure, and ownership structure and exercise of control rights. A key factor in a customer's decision to engage a corporation is the confidence that expectations will be met. For cloud services, the interdependencies of services should not hinder the customer from clearly identifying the responsible parties. Stakeholders should carefully consider the monitoring mechanisms that are appropriate and necessary for the company's consistent performance and growth.

Customers should review the specific information security governance structure and processes, as well as specific security controls, as part of their due diligence for future cloud providers. The provider's security governance processes and capabilities should be evaluated to see if they are consistent with the customer's information security management processes. The cloud provider's information security controls should be risk-based and clearly support the customer's management processes. The loss of control and governance could cause noncompliance with the security requirements, a lack of confidentiality, integrity and availability of data, and a worsening of performance and quality of service.

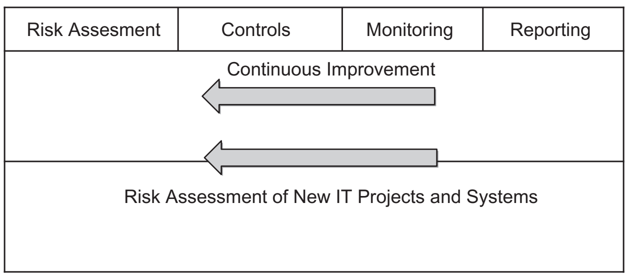

FIGURE 6.8 Cycle of compliance evaluation.

Retaining Responsibility for the Accuracy of the Data

Laws and regulations will usually determine who in an organization should be responsible and held accountable for the accuracy and security of the data. If the customer is storing HIPAA (Health Insurance Portability and Accountability Act) data, then the customer must have a security-related post created to ensure compliance. The Sarbanes–Oxley Act assigns the Chief Financial Officer (CFO) and Chief Executive Officer (CEO) joint responsibility for the financial data. The Gramm-Leach-Bliley Act (GLBA) casts a wider net, making the entire board of directors responsible for security. The Federal Trade Commission (FTC) is less specific by only requiring a certain individual to be responsible for information security in a company.

Verifying Integrity in Stored and Transmitted Data

One of the main difficulties in cloud computing is tracking the location of data during processing. Having control over the data's creation, transfer, storage, use, and destruction becomes crucial. Using data-mining tools and solid IT operational practices will be key to managing data. Although host-level security can be tackled, host-to-host communication and its integrity are harder to secure due to the volume and dynamic nature of data in transition. Although traditional security scanners can be used, real-time reporting provides a better assessment. Thus, an IT GRC solution would display a general view of important metrics to provide a summary of site security and reliability. This solution can keep track of version management and integrity verification of backed-up and in-transit data.

Demonstrating Due Care and Due Diligence

Before signing a contract with a cloud provider, a customer should assess its specific requirements. The range of the services, along with any limitations, regulations, or compliance requirements, should be identified. Any

services that will be deployed to the cloud should also be graded as to their importance to the business. A customer should consider if cloud computing is a true core business of the provider, if the provider is financially sound, if the provider is outsourcing, if the physical security of the facilities meet customer needs, if the provider's BC and DR plans are consistent with the customer's needs, if the operations team is technically competent, if they have a verifiable track record, and if the provider offers any indemnifications. Performing due diligence will reduce the negotiation time and make sure that the correct level of security is in place for the customer.

Supporting Electronic Discovery

Electronic discovery (e-discovery) refers to discovery in civil litigation of information in an electronic format. Due to the nature of a cloud environment, a customer might not be able to apply or use e-discovery tools regularly used. The customer also might not have the capability or administrative permissions to search or access all of the data existing in the cloud. Therefore, the customer will need to take into consideration the additional time and expense that will result from performing e-discovery in a cloud environment.

The customers must make clear in the contractual agreement what the cloud provider needs to do if they are contacted to provide data to a third party, such as law enforcement. The customers might want to contest the request due to the confidentiality of the data or due to an unreasonable request.

Preserving a Chain of Evidence

Chain of evidence or chain of custody refers to the chronological documentation showing seizure, custody, control, transfer, analysis, and disposition of evidence. Several issues touch on the responsibilities and limits that affect customers and providers with regard to collecting legally admissible evidence for prosecution. Identifying the actors is difficult enough with an evidence chain where responsibility for collecting data is shared between the provider and tenant. One party may be the custodian of the data, while the other is the legal owner. Maintaining a chain of evidence can be difficult due to the possibility of compromising the privacy of other cloud customers, unsynchronized log times, and data tampering in open environments, such as public clouds.

Assuring Compliance with Government Certification and Accreditation Regulations

Cloud providers face an increasingly complex variety of compliance requirements from their customers, such as industry standards, regulations, and customer frameworks. Relevant audit frameworks should be used when designing the cloud provider's security control set, and periodic external audits should address the most relevant aspects of these controls.

HIPAA

Cloud providers and customers that handle protected health information (PHI) are required to comply with the security and privacy requirements established in support of HIPAA. The HIPAA security and privacy rules focus on health plans, health care clearinghouses, health care providers, and system vendors. HIPAA requires that PHI is sufficiently protected when entrusted to third parties, such as cloud providers. The level of security should be kept up to standard across all environments. HIPAA addresses administrative safeguards, workforce security, information access management, security awareness and training, security incident procedures, contingency plans, evaluations, physical safeguards (facility and user devices), and technical safeguards (access control, audit control and integrity, authentication, and encryption).

Sarbanes–Oxley

As a reaction to substantial financial reporting fraud in the early 2000s, the Sarbanes–Oxley Act of 2002 (SOX) was passed and signed into law. As a result of SOX, public company CFOs and CEOs are required to certify the efficacy of their internal controls over financial reporting (ICOFR) on a quarterly and annual basis. Management is required to do a yearly assessment of its ICOFR. Third-party auditors are required to provide an opinion about the efficacy of the management's ICOFR at the company's fiscal year end. SOX also influenced the creation of the Public Company Accounting Oversight Board (PCAOB), which was tasked with instituting audit standards. PCAOB Auditing Standard No. 2 pointed to the significance of information technology general controls (ITGCs).

SOX emphasizes the efficacy of an organization's financial reporting process, accounting and finance processes, other vital business, and controls over IT systems that have a material influence on financial reporting. SOX includes internally administered and outsourced systems that can substantially affect financial reporting. A customer using a SaaS environment might make the cloud provider relevant to their SOX scope if financial information is processed in the cloud. Cloud providers need to be clear about their own and the customer's responsibilities about processing information and ensure robust processes for user management/segregation of duties, systems development, program and infrastructure change

An Agenda for Action for Complying with the Data Protection Act Activities

All UK businesses holding personal data about third parties (customers) must comply with the Data Protection Act. The act's principles are as follows (check all tasks completed):

_____**1.** Personal data shall be processed fairly and lawfully and, in particular, shall not be processed unless:

_____**a.** at least one of the conditions in Schedule 2 is met, and

_____**b.** in the case of sensitive personal data, at least one of the conditions in Schedule 3 is also met.

_____**2.** Personal data shall be obtained only for one or more specified and lawful purposes, and shall not be further processed in any manner incompatible with that purpose or those purposes.

_____**3.** Personal data shall be adequate, relevant, and not excessive in relation to the purpose or purposes for which they are processed.

_____**4.** Personal data shall be accurate and, where necessary, kept up to date.

_____**5.** Personal data processed for any purpose or purposes shall not be kept longer than is necessary for that purpose or those purposes.

_____**6.** Personal data shall be processed in accordance with the rights of data subjects under this Act.

_____**7.** Appropriate technical and organizational measures shall be taken against unauthorized or unlawful processing of personal data and against accidental loss or destruction of, or damage to, personal data.

_____**8.** Personal data shall not be transferred to a country or territory outside the European Economic Area unless that country or territory ensures an adequate level of protection for the rights and freedoms of data subjects in relation to the processing of personal data.

management, and computer operations. Cloud providers also need to be concerned about physical security; stored and in-transit data; passwords; remote access; provider access to data; data disclosure; other customers accessing the data; data location (data centers, replicas, backups); shared resources; loss of governance; and isolation failures.

Data Protection Act

The Data Protection Act of 1998 is a United Kingdom (UK) Act of Parliament. The Act, defines UK law on the processing of data on identifiable living people (see the checklist: An Agenda for Action for Complying with the Data Protection Act Activities).

PCI DSS

Organizations that deal with credit-card transactions are required to comply with the Payment Card Industry (PCI) Data Security Standard (DSS). The compliance is ensured by third-party assessments and self-assessments, depending on the volume of credit-card processing transactions. PCI DSS contains 12 high-level requirements:

1. Install and maintain a firewall configuration to protect cardholder data.
2. Do not use vendor-supplied defaults for system passwords and other security parameters.
3. Protect stored cardholder data.
4. Encrypt transmission of cardholder data across open, public networks.
5. Use and regularly update antivirus software.
6. Develop and maintain secure systems and applications.
7. Restrict access to cardholder data based on the business's need to know.
8. Assign a unique ID to each person with computer access.
9. Restrict physical access to cardholder data.
10. Track and monitor all access to network resources and cardholder data.
11. Regularly test security systems and processes.
12. Maintain a policy that addresses information security.

Customers processing or storing cardholder data in a cloud provider need to ensure that the cloud provider and other third parties comply with PCI DSS as well. If the cloud provider has services including processing of credit-card transactions, it is crucial that the cloud provider transparently explains its information flows and how it segregates its credit-card processing and storage activities from others. This approach would limit the extent of the infrastructure that would be subject to PCI DSS. The main objectives of PCI DSS are to ensure the protection of cardholder data, avert breaches, and rapidly contain a breach. These objectives are valid for cloud computing environments as well.

Limiting the Geographic Location of Data

Cloud customers need to ensure that the providers employed outside of their country of residence and jurisdiction have sufficient security controls in place, including their primary and backup sites as well as any

intermediate sites that the data crosses. The data protection laws of the European Union (EU) states and other countries are complex and have numerous requirements. The EU stipulates that the data controller and processor must notify entities that the data will be sent and processed in a country other than a member state. They must also have contracts approved by the Data Protection Authority before these activities can be performed. The customer also needs to be aware of the cloud provider subcontracting any data-related functionality since the third parties involved might host or transfer data outside of the customer's jurisdiction.

Following Standards for Auditing Information Systems

Due to multi-tenancy and shared environments, it becomes difficult to conduct an audit without the cloud provider breaching the confidentiality of other customers sharing the infrastructure. In such cases, the cloud provider should adopt a compliance program based on standards such as ISO27001 and provide assurance via SysTrust or ISO certification to its customers. Some audit frameworks are as follows:

- *SAS 70*: This framework involves the audit of controls based on control objectives and control activities (defined by the cloud provider). The auditor provides opinion on the design, operational status, and operating effectiveness of controls. SAS 70 intends to cover services that are relevant for purposes of customers' financial statement audits.
- *SysTrust*: This framework involves the audit of controls based on defined principles and criteria for security, availability, confidentiality, and processing integrity. SysTrust applies to the reliability of any system.
- *WebTrust*: This framework involves the audit of controls based on defined principles and criteria for security, availability, confidentiality, processing integrity, and privacy. WebTrust applies to online or e-commerce systems.
- *ISO 27001*: This framework involves the audit of an organization's Information Security Management System (ISMS).

Negotiating Third-party Provider Audits

When customers engage an audit provider, they should involve proper legal, procurement, and contract teams within their organization. The customer should consider specific compliance requirements and when negotiating must agree on how to collect, store, and share compliance evidence (e.g., audit logs, activity reports, system configurations). If the standard terms of services do not address the customer's compliance needs, they will need to be negotiated. Contracts should include the involvement of a third party for the review of SLA metrics and compliance (e.g., by a mutually selected mediator). Customers should prefer auditors with expertise in cloud computing who are familiar with the assurance challenges of cloud computing environments. Customers should request the cloud provider's SSAE 16 SOC2 (Statements on Standards for Attestation Engagements No. 16 Service Organization Control 2) or ISAE 3402 Type 2 (International Standard on Assurance Engagements 3402 Type 2) reports to provide a starting point of reference for auditors. SSAE 16 SOC2 provides a standard benchmark by which two data center audit reports can be compared and the customer can be assured that the same set of criteria was used to evaluate each. An ISAE 3402 Type 2 Report is known as the report on the description, design, and operating effectiveness of controls at a service organization.

8. PREPARING FOR DISASTER RECOVERY

To make sure the availability of cloud services, business continuity, and disaster recovery address a broad set of activities that are performed. Business continuity is based on standards, policies, guidelines, and procedures that facilitate continuous operation regardless of the incidents. Disaster recovery (DR) is a subsection of business continuity and is concerned with data and IT systems.

Implementing a Plan to Sustain Availability

A cloud service provider (CSP) should have a formal disaster recovery plan in place to assure the provider's viability against natural disasters, human errors, and malicious behavior. This plan should be continuously tested to ensure preparedness and should not compromise the security of the cloud in the event of a disaster.

Customers should review their contracts with the cloud provider and third parties to confirm and verify that the disaster recovery controls and certifications are in place. Customers could also conduct on-site assessments if found necessary. The cloud provider should inform the customer in advance about any disaster recovery tests.

Reliably Connecting to the Cloud across the Public Internet

There may be a substantial amount of latency between the customer's processing and the data stored in the cloud. Contingent on the amount of data being handled, this can result in unacceptable performance. If users access the data in the cloud, the latency may also cause an intolerable user experience. Wide area network optimization between the customer and the cloud provider

should be in place so that the cloud enables full data mobility at reduced bandwidth, storage utilization, and cost. These performance issues might be managed with a combination of increased bandwidth or by traffic management. An alternative method is to utilize a cloud storage gateway. An issue to contemplate with a cloud storage gateway is the difference between tiering and caching. The gateways that use the caching method use cloud storage as their primary storage location. On the other hand, the gateways that utilize the tiering method use on-site storage as their primary storage and cloud storage as their secondary storage.

Anticipating a Sudden Provider Change or Loss

Some CSPs will unavoidably cease operating, therefore, making access to the data in the cloud an issue. Access to data might also be jeopardized if the provider or third party dealing with data breaches the contract and does not provide the promised services. When this happens, the customer's efforts should be directed toward finding a replacement cloud provider and confidentially removing and transferring the data from the defunct provider. It is important to clearly state the handling of data in case of bankruptcy or breach of contract in the SLA. Confidential data should be removed properly without leaving any trace.

Archiving SaaS Data Locally

Customers should perform regular extractions and backups to a format that is provider agnostic and make sure metadata can be preserved and migrated. It is also important to understand if any custom tools will have to be developed or if the provider will provide the migration tools. For legal and compliance reasons, the customer should ensure that backups and copies of logs, access records, and any other pertinent information are included in the archive as well.

Addressing Data Portability and Interoperability in Preparation for a Change in Cloud Providers

Depending on the application, it is important to integrate with applications that may be present in other clouds or on traditional infrastructure. Interoperability standards either enable or become a barrier to interoperability, and permit maintenance of the integrity and consistency of an organization's information and processes. SLAs should address the steps to change providers from a portability perspective. The customer should have a good understanding of the cloud provider's APIs, hypervisors, application logic, and other restrictions and build processes to migrate to and handle different cloud architectures. Security should be maintained across migrations. Authentication and IAM mechanisms for user or process access to systems now must operate across all components of a cloud system. Using open standards for identity such as SAML will help to ensure portability. Encryption keys should be stored locally. When moving files and their metadata to new cloud environments, the customer should ensure that copies of file metadata are securely removed to prevent this information from remaining behind and opening a possible opportunity for compromise.

Exploiting the Cloud for Efficient Disaster Recovery Options

Besides providing all the advantages discussed in this chapter, cloud computing has brought advantages in the form of online storage. This feature can be leveraged for backup and disaster recovery and can reduce the cost of infrastructure, applications, and overall business processes. Many cloud storage providers guarantee the reliability and availability of their service. The challenges to cloud storage, cloud backup, and DR in particular involve mobility, information transfer, and availability, assuring business continuity, scalability, and metered payment. Cloud disaster recovery solutions are built on the foundation of three fundamentals: a virtualized storage infrastructure, a scalable file system, and a self-service disaster recovery application that responds to customers' urgent business needs. Some vendors that provide cloud storage services are Amazon, Google, Terremark, and Rackspace.

Achieving Cost-effective Recovery Time Objectives

Recovery Time Objective (RTO) is the maximum amount of time that is acceptable for restoring and regaining access to data after a disruption. To keep RTO low, cloud-based DR requires ongoing server replication, making network bandwidth an important consideration when adopting this approach. To keep bandwidth requirements and related costs low, customers need to identify their critical systems and prioritize them in their DR plan. Focusing on a narrower set of systems will make DR more efficient and more cost effective by keeping complexity and network bandwidth low.

Employing a Strategy of Redundancy to Better Resist DoS

Denial-of-service (DoS), or distributed-denial-of-service (DDoS) attack, is a type of network-based attack that attempts to make computer or network resources unavailable to their intended users. Customers and cloud providers should ensure that their systems have effective security processes and controls in place so that they can

withstand DoS attacks. The controls and processes should have the ability to recognize a DoS attack and utilize the provider's local capacity and geographical redundancies to counter the attack's excessive use of network bandwidth (SYN or UDP floods), CPU, memory, and storage resources (application attacks).

Techniques such as cloudbursting can be used to mitigate the unexpected increase in resource consumption. Third-party cloud-based DDoS mitigation services (e.g., Akamai, Verisign) can be used to offload server functionality, defend the application layer, offload infrastructure functions, obfuscate infrastructure, protect DNS services, and failover gracefully when an attack is overwhelming.

9. SUMMARY

We have seen that cloud computing offers a service or deployment model for almost every type of customer and that each flavor comes with its own security concerns. Advantages offered by cloud solutions need to be weighed with the risks they entail. While public clouds are great for commercial customers, federal customers or other customers dealing with sensitive data need to consider private or hybrid cloud solutions. We have also seen the importance of embodying customer security requirements in SLAs to protect interests for compliance, DR, and other concerns. While delegation of resource management and procurement is a great advantage of cloud computing, customers are still accountable for the security and privacy of the deployed systems and data.

Cloud computing is a new technology that is still emerging. The challenges that appear in the realm of security are being addressed by security experts. If an organization plans to move to a cloud environment, it should do so with caution and weigh the risks to be able to enjoy the low-cost flexibility offered by this empowering technology.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? SaaS, PaaS, and IaaS are SPI models.
2. True or False? The risk-based approach is recommended for organizations considering the cloud.
3. True or False? The data and resources asset(s) is supported by the cloud.
4. True or False? A customer hosts its own application and data, while hosting a part of the functionality in the cloud. This service model is referred to as SaaS.
5. True or False? A customer's first step in evaluating its risks while considering a cloud deployment would be to select the data or function that's going to be hosted in the cloud.

Multiple Choice

1. In the criteria to evaluate a potential cloud service model or provider, a customer should consider:
   A. Comfort level for moving to the cloud
   B. Level of control at each SPI cloud model
   C. Importance of assets to move to the cloud
   D. Type of assets to move to the cloud
   E. All of the above
2. Which attack type can affect an IaaS environment?
   A. Cross-site-request-forgery attacks
   B. Side-channel attacks (VM-to-VM)
   C. Token stealing
   D. Canonicalization attacks
   E. All of the above
3. What should a cloud customer prefer for DR?
   A. High RTO, low cost
   B. Low RTO, high cost
   C. Low RTO, low cost, all data
   D. Backup critical data with a low RTO and cost
   E. All of the above
4. Which deployment model is suitable for a customer that needs the flexibility and resources of a public cloud, but needs to secure and define its networks?
   A. Hybrid
   B. Private
   C. Secured
   D. Virtual Private
   E. All of the above
5. What does an SLA cover?
   A. Service levels
   B. Security
   C. Governance
   D. Compliance
   E. All of the above

EXERCISE

Problem

Does the cloud solution offer equal or greater data security capabilities than those provided by your organization's data center?

Hands-On Projects

Project

Have you taken into account the vulnerabilities of the cloud solution?

Case Projects

Problem

As a project to build a small cloud environment, how do you set up a VPC environment on the Amazon EC2 platform ?

Optional Team Case Project

Problem

Have you considered that incident detection and response can be more complicated in a cloud-based environment?

Fault Tolerance and Resilience in Cloud Computing Environments

Vincenzo Piuri
Universita' degli Studi di Milano

1. INTRODUCTION

Cloud computing is gaining an increasing popularity over traditional information processing systems. Service providers have been building massive data centers that are distributed over several geographical regions to efficiently meet the demand for their Cloud-based services [1−3]. In general, these data centers are built using hundreds of thousands of commodity servers, and virtualization technology is used to provision computing resources (by delivering Virtual Machines—VMs—with a given amount of CPU, memory, and storage capacity) over the Internet by following the pay-per-use business model [4]. Leveraging the economies of scale, a single physical host is often used as a set of several virtual hosts by the service provider, and benefits such as the semblance of an inexhaustible set of available computing resources are provided to the users. As a consequence, an increasing number of users are moving to cloud-based services for realizing their applications and business processes.

The use of commodity components, however, exposes the hardware to conditions for which it was not originally designed [5,6]. Moreover, due to the highly complex nature of the underlying infrastructure, even carefully engineered data centers are subject to a large number of failures [7]. These failures evidently reduce the overall reliability and availability of the cloud computing service. As a result, fault tolerance becomes of paramount importance to the users as well as the service providers to ensure correct and continuous system operation even in the presence of an unknown and unpredictable number of failures.

The dimension of risks in the user's applications deployed in the virtual machine instances in a cloud has also changed since the failures in data centers are normally outside the scope of the user's organization. Moreover, traditional ways of achieving fault tolerance require users to have an in-depth knowledge of the underlying mechanisms, whereas, due to the abstraction layers and business model of cloud computing, a system's architectural details are not widely available to the users. This implies that traditional methods of introducing fault tolerance may not be very effective in the cloud computing context, and there is an increasing need to address users' reliability and availability concerns.

The goal of this chapter is to develop an understanding of the nature, numbers, and kind of faults that appear in typical cloud computing infrastructures, how these faults impact users' applications, and how faults can be handled in an efficient and cost-effective manner. To this aim, we first describe the fault model of typical cloud computing environments on the basis of system architecture, failure characteristics of widely used server and network components, and analytical models. An overall understanding of the fault model may help researchers and developers to build more reliable cloud computing services. In this chapter, we also introduce some basic and general concepts on fault tolerance and summarize the parameters that must be taken into account when building a fault tolerant system. This discussion is followed by a scheme in which different levels of fault tolerance can be achieved by users' applications by exploiting the properties of the cloud computing architecture.

In this chapter, we discuss a solution that can function in users' applications in a general and transparent manner to tolerate one of the two most frequent classes of faults that appear in the cloud computing environment. We also present a scheme that can tolerate the other class of frequent faults while reducing the overall resource costs by half when compared to existing solutions in the literature. These two techniques, along with the concept of different fault tolerance levels, are used as the basis for developing a methodology and framework that offers fault tolerance as an

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00007-6

additional service to the user's applications. We believe that the notion of offering fault tolerance as a service may serve as an efficient alternative to traditional approaches in addressing user's reliability and availability concerns.

2. CLOUD COMPUTING FAULT MODEL

In general, a failure represents the condition in which the system deviates from fulfilling its intended functionality or the expected behavior. A failure happens due to an error, that is, due to reaching an invalid system state. The hypothesized cause for an error is a fault, which represents a fundamental impairment in the system. The notion of faults, errors, and failures can be represented using the following chain [8,9]:

...Fault → Error → Failure → Fault → Error → Failure...

Fault tolerance is the ability of the system to perform its function even in the presence of failures. This implies that it is utmost important to clearly understand and define what constitutes the correct system behavior so that specifications on its failure characteristics can be provided and consequently a fault tolerant system can be developed. In this section, we discuss the fault model of typical cloud computing environments to develop an understanding of the numbers as well as the causes behind recurrent system failures. In order to analyze the distribution and impact of faults, we first describe the generic cloud computing architecture.

Cloud Computing Architecture

Cloud computing architecture comprises four distinct layers as illustrated in Figure 7.1 [10]. Physical resources (blade servers and network switches) are considered the lowest-layer in the stack, on top of which virtualization and system management tools are embedded to form the infrastructure-as-a-service (IaaS) layer. Note that the infrastructure supporting large-scale cloud deployments is typically the data centers, and virtualization technology is used to maximize the use of physical resources, application isolation, and quality of service. Services offered by IaaS are normally accessed through a set of user-level middleware services that provide an environment to simplify application development and deployment (Web 2.0 or higher interfaces, libraries, and programming languages). The layer above the IaaS that binds all user-level middleware tools is referred to as platform-as-a-service (PaaS). User-level applications (social networks and scientific models) that are built and hosted on top of the PaaS layer comprise the software-as-a-service (SaaS) layer.

Failure in a given layer normally has an impact on the services offered by the layers above it. For example, failure in a user-level middleware (PaaS) may produce errors in the software services built on top of it (SaaS applications). Similarly, failures in the physical hardware or the IaaS layer will have an impact on most PaaS and SaaS services. This implies that the impact of failures in the IaaS layer or the physical hardware is significantly high; hence, it is important to characterize typical hardware faults and develop corresponding fault tolerance techniques.

We describe the failure behavior of various server components based on the statistical information obtained from large-scale studies on data center failures using data mining techniques [6,11] and analyze the impact of component failures on users' applications by means of analytical models such as fault trees and Markov chains [12]. Similar to server components, we also present the failure behavior of network component failures.

Failure Behavior of Servers

Each server in the data center typically contains multiple processors, storage disks, memory modules, and network interfaces. The study about server failure and hardware repair behavior is to be performed using a large collection of servers (approximately 100,000 servers) and corresponding data on part replacement such as details about server configuration, when a hard disk was issued a ticked for replacement, and when it was actually replaced. Such a data repository, which included server collection spanning multiple data

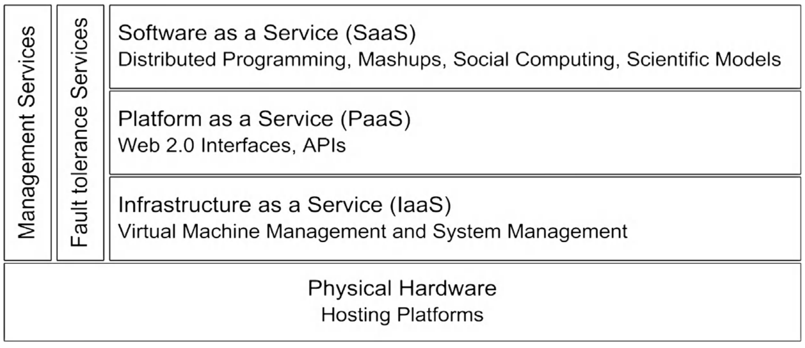

FIGURE 7.1 Layered architecture of cloud computing.

centers distributed across different countries, is gathered [6]. Key observations derived from this study are as follows:

- 92 percent of the machines do not see any repair events, but the average number of repairs for the remaining 8 percent is 2 per machine (20 repair/replacement events contained in nine machines were identified over a 14-month period). The annual failure rate (AFR) is therefore around 8 percent.
- For an 8 percent AFR, repair costs that amounted to $2.5 million are approximately spent for 100,000 servers.
- About 78 percent of total faults/replacements were detected on hard disks, 5 percent on RAID controllers, and 3 percent due to memory failures. Thirteen percent of replacements were due to a collection of components (not particularly dominated by a single component failure). Hard disks are clearly the most failure-prone hardware components and the most significant reason behind server failures.
- About 5 percent of servers experience a disk failure in less than one year from the date when it is commissioned (young servers), 12 percent when the machines are one year old, and 25 percent when they are two years old.
- Interestingly, based on the chi-squared automatic interaction detector methodology, none of the following factors—age of the server, its configuration, location within the rack, and workload run on the machine—were found to be a significant indicator for failures.
- Comparison between the number of repairs per machine (RPM) to the number of disks per server in a group of servers (clusters) indicates that (i) there is a relationship in the failure characteristics of servers that have already experienced a failure, and (ii) the number of RPM has a correspondence to the total number of disks on that machine.

Based on these statistics, it can be inferred that robust fault tolerance mechanisms must be applied to improve the reliability of hard disks (assuming independent component failures) to substantially reduce the number of failures. Furthermore, to meet the high availability and reliability requirements, applications must reduce utilization of hard disks that have already experienced a failure (since the probability of seeing another failure on that hard disk is higher).

The failure behavior of servers can also be analyzed based on the models defined using fault trees and Markov chains [12,13]. The rationale behind the modeling is twofold: (1) to capture the user's perspective on component failures, that is, to understand the behavior of users' applications that are deployed in the VM instances under server component failures and (2) to define the correlation between individual component failures and the boundaries on the impact of each failure. An application may have an impact when there is a failure/error either in the

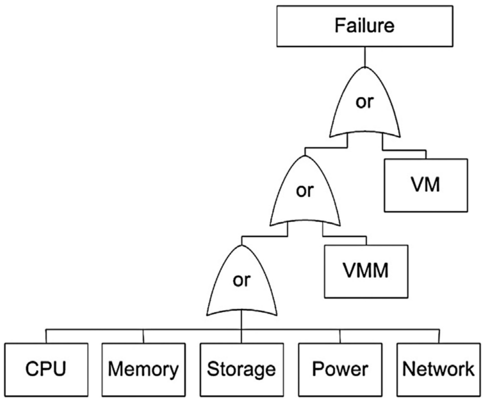

FIGURE 7.2A Fault tree characterizing server failures [12].

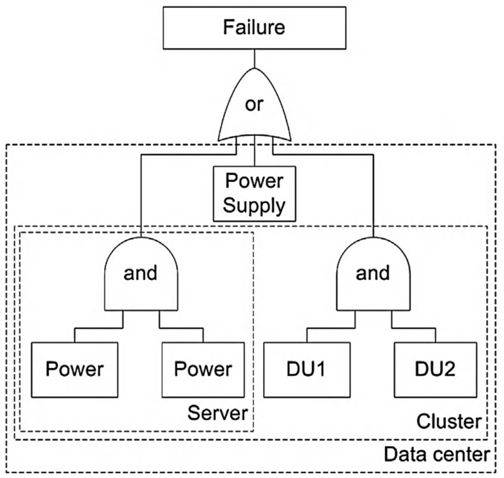

FIGURE 7.2B Fault tree characterizing power failures [12].

processor, memory modules, storage disks, power supply (see Figure 7.2b) or network interfaces of the server, or the hypervisor, or the VM instance itself. Figure 7.2a illustrates this behavior as a fault tree where the top-event represents a failure in the user's application. The reliability and availability of each server component must be derived using Markov models that are populated using long-term failure behavior information [6].

Failure Behavior of the Network

It is important to understand the overall network topology and various network components involved in constructing a data center so as to characterize the network failure behavior (see Figure 7.3b). Figure 7.3a illustrates an example of partial data center network architecture [11,14]. Servers are connected using a set of network switches and routers. In particular, all rack-mounted servers are first connected via a 1 Gbps link to a top-of-rack switch (ToR), which is in turn connected to two (primary

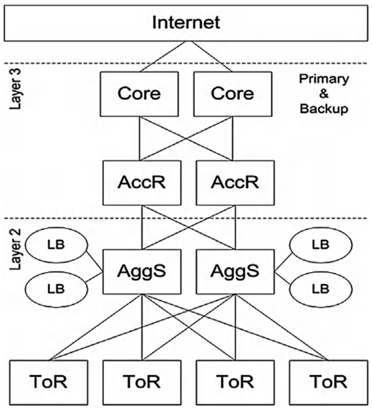

FIGURE 7.3A Partial network architecture of a data center [11].

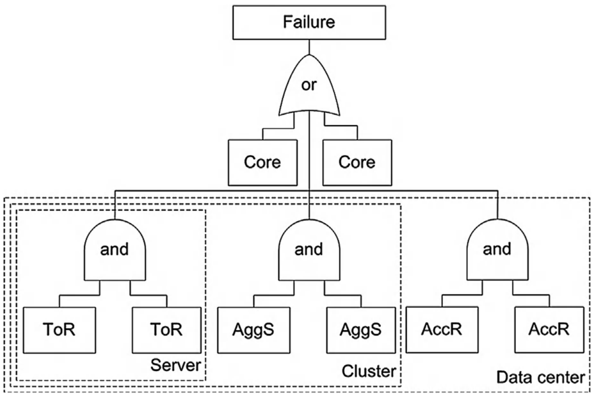

FIGURE 7.3B Fault tree characterizing network failures [12].

and backup) aggregation switches (AggS). An AggS connects tens of switches (ToR) to redundant access routers (AccR). This implies that each AccR handles traffic from thousands of servers and routes it to core routers that connect different data centers to the Internet [11,12]. All links in the data centers commonly use Ethernet as the link layer protocol, and redundancy is applied to all network components at each layer in the network topology (except for ToRs). In addition, redundant pairs of load balancers (LBs) are connected to each AggS, and mapping between static IP address presented to the users and dynamic IP addresses of internal servers that process user's requests is performed. Similar to the study on failure behavior of servers, a large-scale study on network failures in data centers is performed [11]. A link failure happens when the connection between two devices on a specific interface is down, and a device failure happens when the device is not routing/forwarding packets correctly (due to power outage or hardware crash). Key observations derived from this study are as follows:

- Among all the network devices, load balancers are least reliable (with failure probability of 1 in 5) and ToRs are most reliable (with a failure rate of less than 5 percent). The root causes for failures in LBs are mainly the software bugs and configuration errors (as opposed to the hardware errors for other devices). Moreover, LBs tend to experience short but frequent failures. This observation indicates that low-cost commodity switches (ToRs and AggS) provide sufficient reliability.
- The links forwarding traffic from LBs have the highest failure rates; links higher in the topology (connecting AccRs) and links connecting redundant devices have the second highest failure rates.
- The estimated median number of packets lost during a failure is 59 K, and the median number of bytes is 25 MB (the average size of lost packets is 423 Bytes). Based on prior measurement studies (that observe packet sizes to be bimodal with modes around 200 Bytes and 1400 Bytes), it is estimated that most lost packets belong to the lower part (ping messages or ACKs).
- Network redundancy reduces the median impact of failures (in terms of number of lost bytes) by only 40 percent. This observation is against the common belief that network redundancy completely masks failures from applications.

Therefore, the overall data center network reliability is about 99.99 percent for 80 percent of the links and 60 percent of the devices. Similar to servers, Figure 7.3b represents the fault tree for the user's application failure with respect to network failures in the data center. A failure occurs when there is an error in all redundant switches ToRs, AggS, AccR, or core routers, or the network links connecting physical hosts. Since the model is designed in the user's perspective, a failure in this context implies that the application is not connected to the rest of the network or gives errors during data transmission. Through use of this modeling technique, the boundaries on the impact of each network failure can be represented (using server, cluster, and data center level blocks) and can further be used to increase the fault tolerance of the user's application (by placing replicas of an application in different failure zones).

3. BASIC CONCEPTS ON FAULT TOLERANCE

In general, the faults we analyzed in the last section can be classified in different ways depending on the nature of the system. Since, in this chapter, we are interested in typical cloud computing environment faults that appear as failures to the end users, we classify the faults into two types similarly to other distributed systems:

- *Crash faults* that cause the system components to completely stop functioning or remain inactive during failures (power outage, hard disk crash).

- *Byzantine faults* that lead the system components to behave arbitrarily or maliciously during failure, causing the system to behave unpredictably incorrect.

As observed previously, fault tolerance is the ability of the system to perform its function even in the presence of failures. It serves as one of the means to improve the overall system's dependability. In particular, it contributes significantly to increasing the system's reliability and availability.

The most widely adopted methods to achieve fault tolerance against crash faults and byzantine faults are as follows:

- *Checking and monitoring*: The system is constantly monitored at runtime to validate, verify, and ensure that correct system specifications are being met. This technique, though very simple, plays a key role in failure detection and subsequent reconfiguration.
- *Checkpoint and restart*: The system state is captured and saved based on predefined parameters (after every 1024 instructions or every 60 seconds). When the system undergoes a failure, it is restored to the previously known correct state using the latest checkpoint information (instead of restarting the system from start).
- *Replication*: Critical system components are duplicated using additional hardware, software, and network resources in such a way that a copy of the critical components is available even after a failure happens. Replication mechanisms are mainly used in two formats: active and passive. In active replication, all the replicas are simultaneously invoked and each replica processes the same request at the same time. This implies that all the replicas have the same system state at any given point of time (unless designed to function in an asynchronous manner) and it can continue to deliver its service even in case of a single replica failure. In passive replication, only one processing unit (the primary replica) processes the requests, while the backup replicas only save the system state during normal execution periods. Backup replicas take over the execution process only when the primary replica fails.

Variants of traditional replication mechanisms (active and passive) are often applied on modern distributed systems. For example, the semiactive replication technique is derived from traditional approaches wherein primary and backup replicas execute all the instructions but only the output generated by the primary replica is made available to the user. Output generated by the backup replicas is logged and suppressed within the system so that it can readily resume the execution process when the primary replica failure happens. Figure 7.4a depicts the Markov model of a system that uses an active/semiactive replication scheme with two replicas [12]. This model serves as an effective means of deriving the reliability and availability of the system because the failure behavior of both replicas can be taken into account. Moreover, as described earlier, the results of the Markov model analysis can be used to support the fault trees in characterizing the impact of failures in the system. Each state in the model is represented by a pair (x, y) where $x = 1$ denotes that the primary replica is working and $x = 0$ implies that it failed. Similarly, y represents the working condition of the backup replica. The system starts and remains in state (1,1) during normal execution, that is, when both the replicas are available and working correctly. A failure either in the primary or the backup replica moves the system to state (0,1) or (1,0) where the other replica takes over the execution process. A single state is sufficient to represent this condition in the model since both replicas are consistent with each other. The system typically initiates its recovery mechanism in state (0,1) or (1,0), and moves to state (1,1) if the recovery of the failed replica is successful; otherwise it transits to state (0,0) and becomes completely unavailable. Similarly, Figure 7.4b illustrates the Markov model of the system for which a passive replication scheme is applied. λ denotes the failure rate, μ denotes the recovery rate, and k is a constant.

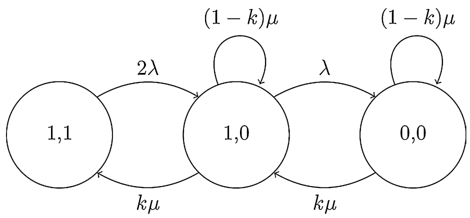

FIGURE 7.4A Markov model of a system with two replicas in active/semiactive replication scheme [12].

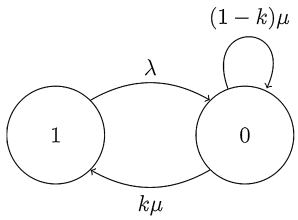

FIGURE 7.4B Markov model of a system with two replicas in passive replication scheme [12].

Fault tolerance mechanisms are varyingly successful in tolerating faults [15]. For example, a passively replicated system can tolerate only crash faults, whereas actively replicated system using $3f + 1$ replicas are capable of tolerating byzantine faults. In general, mechanisms that handle failures at a finer granularity, offering higher performance guarantees, also consume higher amounts of

resources [16]. Therefore, the design of fault tolerance mechanisms must take into account a number of factors such as implementation complexity, resource costs, resilience, and performance metrics, and achieve a fine balance of the following parameters:

- *Fault tolerance model*: Measures the strength of the fault tolerance mechanism in terms of the granularity at which it can handle errors and failures in the system. This factor is characterized by the robustness of failure detection protocols, state synchronization methods, and strength of the fail-over granularity.
- *Resource consumption*: Measures the amount and cost of resources that are required to realize a fault tolerance mechanism. This factor is normally inherent with the granularity of the failure detection and recovery mechanisms in terms of CPU, memory, bandwidth, I/O, and so on.
- *Performance*: Deals with the impact of the fault tolerance procedure on the end-to-end quality of service (QoS) both during failure and failure-free periods. This impact is often characterized using fault detection latency, replica launch latency, failure recovery latency, and other application-dependent metrics such as bandwidth, latency, and loss rate.

We build on the basic concepts discussed in this section to analyze the fault tolerance properties of various schemes designed for cloud computing environment.

4. DIFFERENT LEVELS OF FAULT TOLERANCE IN CLOUD COMPUTING

As discussed earlier, server components in a cloud computing environment are subject to failures, affecting users' applications, and each failure has an impact within a given boundary in the system. For example, a crash in the pair of aggregate switches may result in the loss of communication among all the servers in a cluster; in this context, the boundary of failure is the cluster since applications in other clusters can continue functioning normally. Therefore, while applying a fault tolerance mechanism such as a replication scheme, at least one replica of the application must be placed in a different cluster to ensure that aggregate switch failure does not result in a complete failure of the application. Furthermore, this implies that deployment scenarios (location of each replica) are critical to correctly realize the fault tolerance mechanisms. In this section, we discuss possible deployment scenarios in a cloud computing infrastructure, and the advantages and limitations of each scenario.

Based on the architecture of the cloud computing infrastructure, different levels of failure independence can be derived for cloud computing services [17,18]. Moreover, assuming that the failures in individual resource components are independent of each other, fault tolerance and resource costs of an application can be balanced based on the location of its replicas. Possible deployment scenarios and their properties are as follows.

- *Multiple machines within the same cluster*. Two replicas of an application can be placed on the hosts that are connected by a ToR switch (within a LAN). Replicas deployed in this configuration can benefit in terms of low latency and high bandwidth but obtain very limited failure independence. A single switch or power distribution failure may result in an outage of the entire application, and both replicas cannot communicate to complete the fault tolerance protocol. Cluster- level blocks in the fault trees of each resource component (network failures as shown in Figure 7.3b) must be combined using a logical AND operator to analyze the overall impact of failures in the system. Note that reliability and availability values for each fault tolerance mechanism with respect to server faults must be calculated using a Markov model.
- *Multiple clusters within a data center*. Two replicas of an application can be placed on the hosts belonging to different clusters in the same data center (on the hosts that are connected via a ToR switch and AggS). Failure independence of the application in this deployment context remains moderate since the replicas are not bound to an outage with a single power distribution or switch failure. The overall availability of an application can be calculated using cluster-level blocks from fault trees combined with a logical OR operator in conjunction with power and network using AND operator.
- *Multiple data centers*. Two replicas of an application can be placed on the hosts belonging to different data centers (connected via a switch), AggS and AccR. This deployment has a drawback with respect to high latency and low bandwidth, but offers a very high level of failure independence. A single power failure has the least effect on the availability of the application. The data center level blocks from the fault trees may be connected with a logical OR operator in conjunction with the network in the AND logic.

As an example [13,19], the overall availability of each representative replication scheme with respect to different deployment levels is obtained as shown in Table 7.1. Availability of the system is highest when the replicas are placed in two different data centers. The value declines when replicas are placed in two different clusters within the same data center, and it is lowest when replicas are placed inside the same LAN. The overall availability obtained by semiactive replication is higher than

TABLE 7.1 Availability Values (normalized to 1) for Replication Techniques at Different Deployment Scenarios [12].

	Same Cluster	Same Data Center, diff. Clusters	Diff. Data Centers
Semiactive	0.9871	0.9913	0.9985
Semipassive	0.9826	0.9840	0.9912
Passive	0.9542	0.9723	0.9766

semipassive replication and lowest for the simple passive replication scheme.

As described earlier, effective implementation of fault tolerance mechanisms requires consideration of the strength of the fault tolerance model, resource costs, and performance. While traditional fault tolerance methods require tailoring of each application having an in-depth knowledge of the underlying infrastructure, in the cloud computing scenario, it would also be beneficial to develop methodologies that can generically function on users' applications so that a large number of applications can be protected using the same protocol. In addition to generality, agility in managing replicas and checkpoints to improve the performance, and reduction in the resource consumption costs while not limiting the strength of fault tolerance mechanisms are required.

Although several fault tolerance approaches are being proposed for cloud computing services, most solutions that achieve at least one of the required properties described above are based on virtualization technology. By using virtualization-based approaches, it is also possible to deal with both classes of faults. In particular, in a later section of this chapter we present a virtualization-based solution that provides fault tolerance against crash failures using a checkpointing mechanism. We discuss this solution because it offers two additional, significantly useful, properties: (1) Fault tolerance is induced independent to the applications and hardware on which it runs. In other words, an increased level of generality is achieved since any application can be protected using the same protocol as long as it is deployed in a VM, and (2) mechanisms such as replication, failure detection, and recovery are applied transparently—not modifying the OS or application's source code. Then, we present a virtualization-based solution that uses typical properties of a cloud computing environment to tolerate byzantine faults using a combination of replication and checkpointing techniques. We discuss this solution because it reduces the resource consumption costs incurred by typical byzantine fault tolerance schemes during fail-free periods nearly by half.

5. FAULT TOLERANCE AGAINST CRASH FAILURES IN CLOUD COMPUTING

A scheme that leverages the virtualization technology to tolerate crash faults in the cloud in a transparent manner is discussed in this section. The system or user application that must be protected from failures is first encapsulated in a VM (say active VM or the primary), and operations are performed at the VM level (in contrast to the traditional approach of operating at the application level) to obtain paired servers that run in active–passive configuration. Since the protocol is applied at the VM level, this scheme can be used independent of the application and underlying hardware, offering an increased level of generality. In particular, we discuss the design of *Remus* as an example system that offers the preceding mentioned properties [20]. Remus aims to provide high availability to the applications, and to achieve this, it works in four phases:

1. Checkpoint the changed memory state at the primary, and continue to the next epoch of network and disk request streams.
2. Replicate system state on the backup.
3. Send checkpoint acknowledgment from the backup when complete memory checkpoint and corresponding disk requests have been received.
4. Release outbound network packets queued during the previous epoch upon receiving the acknowledgment.

Remus achieves high availability by frequently checkpointing and transmitting the state of the active VM on to a backup physical host. The VM image on the backup is resident in the memory and may begin execution immediately after a failure in the active VM is detected. The backup only acts like a receptor since the VM in the backup host is not actually executed during fail-free periods. This allows the backup to concurrently receive checkpoints from VMs running on multiple physical hosts (in an N-to-1 style configuration), providing a higher degree of freedom in balancing resource costs due to redundancy.

In addition to generality and transparency, seamless failure recovery can be achieved; that is, no externally visible state is lost in the event of a single host failure and recovery happens rapidly enough that it appears only like a temporary packet loss. Since the backup is only periodically consistent with the primary replica using the checkpoint-transmission procedure, all network output is buffered until a consistent image of the host is received by the backup, and the buffer is released only when the backup is completely synchronized with the primary. Unlike network traffic, the disk state is not externally visible, but it has to be transmitted to the backup as part of a complete cycle. To address this issue, Remus asynchronously sends the disk state to the backup where it is

initially buffered in the RAM. When the corresponding memory state is received, complete checkpoint is acknowledged, output is made visible to the user, and buffered disk state is applied to the backup disk.

Remus is built on Xen hypervisor's live migration machinery [21]. Live migration is a technique through which a complete VM can be relocated onto another physical host in the network (typically a LAN) with a minor interruption to the VM. Xen provides an ability to track guest writes to memory using a technique called shadow page tables. During live migration, memory of the VM is copied to the new location while the VM continues to run normally at the old location. The writes to the memory are then tracked, and the dirtied pages are transferred to the new location periodically. After a sufficient number of iterations, or when no progress in copying the memory is being made (i.e., when the VM is writing to the memory as fast as the migration process), the guest VM is suspended, remaining dirtied memory along with the CPU state is copied, and the VM image in the new location is activated. The total migration time depends on the amount of dirtied memory during guest execution, and total downtime depends on the amount of memory remaining to be copied when the guest is suspended. The protocol design of the system, particularly each checkpoint, can be viewed as the final stop-and-copy phase of live migration. The guest memory in live migration is iteratively copied, incurring several minutes of execution time. The singular stop-and-copy (the final step) operation incurs a very limited overhead—typically in the order of a few milliseconds.

While Remus provides an efficient replication mechanism, it employs a simple failure detection technique that is directly integrated within the checkpoint stream. A timeout of the backup in responding to commit requests made by the primary will result in the primary suspecting a failure (crash and disabled protection) in the backup. Similarly, a timeout of the new checkpoints being transmitted from the primary will result in the backup assuming a failure in the primary. At this point, the backup begins execution from the latest checkpoint. The protocol is evaluated (i) to understand whether or not the overall approach is practically deployable and (ii) to analyze the kind of workloads that are most amenable to this approach.

Correctness evaluation is performed by deliberatively injecting network failures at each phase of the protocol. The application (or the protected system) runs a kernel compilation process to generate CPU, memory, and disk load, and a graphics-intensive client (glxgears) attached to X11 server is simultaneously executed to generate the network traffic. Checkpoint frequency is configured to 25 milliseconds, and each test is performed two times. It is reported that the backup successfully took over the execution for each failure with a network delay of about 1 second when the backup detected the failure and activated the replicated system. The kernel compilation task continued to completion, and glxgears client resumed after a brief pause. The disk image showed no inconsistencies when the VM was gracefully shut down.

Performance evaluation is performed using the SPECweb benchmark that is composed of a Web server, an application server, and one or more Web client simulators. Each tier (server) was deployed in a different VM. The observed scores decrease up to five times the native score (305) when the checkpointing system is active. This behavior is mainly due to network buffering; the observed scores are much higher when network buffering is disabled. Furthermore, it is reported that at configuration rates of 10, 20, 30, and 40 checkpoints per second, the average checkpoint rates achieved are 9.98, 16.38, 20.25, and 23.34, respectively. This behavior can be explained with SPECweb's very fast memory dirtying, resulting in slower checkpoints than desired. The realistic workload therefore illustrates that the amount of network traffic generated by the checkpointing protocol is very large, and as a consequence, this system is not well suited for applications that are very sensitive to network latencies. Therefore, virtualization technology can largely be exploited to develop general-purpose fault tolerance schemes that can be applied to handle crash faults in a transparent manner.

6. FAULT TOLERANCE AGAINST BYZANTINE FAILURES IN CLOUD COMPUTING

Byzantine fault tolerance (BFT) protocols are powerful approaches to obtain highly reliable and available systems. Despite numerous efforts, most BFT systems have been too expensive for practical use; so far, no commercial data centers have employed BFT techniques. For example, the BFT algorithm [22] for asynchronous, distributed, client-server systems requires at least $3f + 1$ replica (one primary and remaining backup) to execute a three-phase protocol that can tolerate f byzantine faults. Note that, as described earlier, systems that tolerate faults at a finer granularity such as the byzantine faults also consume very high amounts of resources, and as already noted, it is critical to consider the resource costs while implementing a fault tolerance solution.

The high resource consumption cost (see Table 7.2) in BFT protocols is most likely due to the way faults are normally handled. BFT approaches typically replicate the server (state machine replication—SMR), and each replica is forced to execute the same request in the same order. This enforcement requirement demands that the server replicas reach an agreement on the ordering of a given set of requests even in the presence of byzantine

TABLE 7.2 Resource Consumption Costs Incurred by Well-Known Byzantine Fault Tolerance Protocols [23].

	PBFT [22]	SEP [25]	Zyzzyva [24]	ZZ [23]
Agreement replicas	$3f+1$	$3f+1$	$3f+1$	$3f+1$
Execution replicas	$3f+1$	$2f+1$	$2f+1$	$(1+r)$ $f+1$

faulty servers and clients. For this purpose, an agreement protocol that is referred to as the *Byzantine Agreement* is used. When an agreement on the ordering is reached, service execution is performed, and majority voting scheme is devised to choose the correct output (and to detect the faulty server). This implies that two clusters of replicas are necessary to realize BFT protocols.

When realistic data center services implement BFT protocols, the dominant costs are due to the hardware performing service execution and not due to running the agreement protocol [23]. For instance, a toy application running *null* requests with the Zyzzyva BFT approach [24] exhibits a peak throughput of 80 K requests/second, while a database service running the same protocol on comparable hardware exhibits almost three times lower throughput. Based on this observation, ZZ, an execution approach that can be integrated with existing BFT SMR and agreement protocols, is presented [23]. The prototype of ZZ is built on the BASE implementation [22] and guarantees BFT, while significantly reducing resource consumption costs during fail-free periods. Table 7.2 compares the resource costs of well-known BFT techniques. Since ZZ provides an effective balance between resource consumption costs and the fault tolerance model, later in this section we discuss its system design in detail.

The design of ZZ is based on the virtualization technology and is targeted to tolerate byzantine faults while reducing the resource provisioning costs incurred by BFT protocols during fail-free periods. The cost reduction benefits of ZZ can be obtained only when BFT is used in the data center running multiple applications, so that sleeping replicas can be distributed across the pool of servers and higher peak throughput can be achieved when execution dominates the request processing cost and resources are constrained. These assumptions make ZZ a suitable scheme to be applied in a cloud computing environment. The system model of ZZ makes the following assumptions similar to most existing BFT systems:

- The service is either deterministic, or nondeterministic operations in the service can be transformed to deterministic ones using an agreement protocol (ZZ assumes a SMR-based BFT system).
- The system involves two kinds of replicas: (1) *agreement replicas* that assign an order to the client's requests and (2) *execution replicas* that execute each client's request in the same order and maintain the application state.
- Each replica fails independently and exhibits byzantine behavior (faulty replicas and clients may behave arbitrarily).
- An adversary can coordinate faulty nodes in an arbitrary manner, but it cannot circumvent standard cryptographic measures (collision-resistant hash functions, encryption scheme, and digital signatures).
  An upper bound g on a number of faulty agreement replicas and f execution replicas is assumed for a given window of vulnerability.
- The system can ensure safety in an asynchronous network, but liveness is guaranteed only during periods of synchrony.

Since the system runs replicas inside virtual machines, to maintain failure independence, it requires that a physical host can deploy at most one agreement and one execution replicas of the service simultaneously. The novelty in the system model is that it considers a byzantine hypervisor. Note that, as a consequence of the above replica placement constraint, a malicious hypervisor can be treated by simply considering a single fault in all the replicas deployed on that physical host. Similarly, an upper bound f on the number of faulty hypervisors is assumed. The BFT execution protocol reduces the replication cost from $2f+1$ to $f+1$ based on the following principle:

- A system that is designed to function correctly in an asynchronous environment will provide correct results even if some of the replicas are outdated.
- A system that is designed to function correctly in the presence of f byzantine faults will, during a fault-free period, remain unaffected even if up to f replicas are turned off.

The second observation is used to commission only an $f+1$ replica to actively execute requests. The system is in a correct state if the response obtained from all $f+1$ replicas is the same. In case of failure (when responses do not match), the first observation is used to continue system operation as if the f standby replicas were slow but correct replicas.

To correctly realize this design, the system requires an agile replica wake-up mechanism. To achieve this mechanism, the system exploits virtualization technology by maintaining additional replicas (VMs) in a "dormant" state, which are either pre-spawned but paused VMs or the VM that is hibernated to a disk. There is a trade-off in

adopting either method. Pre-spawned VM can resume execution in a very short span (in the order of few milliseconds) but consumes higher memory resources, whereas VMs hibernated to disks incur greater recovery times but occupy only storage space. This design also raises several interesting challenges such as *how can a restored replica obtain the necessary application state that is required to execute the current request? How can the replication cost be made robust to faulty replica or client behavior? Does the transfer of an entire application state take an unacceptably long time?*

The system builds on the BFT protocol that uses independent agreement and execution clusters [25]). Let A represent the set of replicas in the agreement cluster, $|A| = 2g + 1$, that runs the three-phase agreement protocol [22]. When a client c sends its request Q to the agreement cluster to process an operation o with timestamp t, the agreement cluster assigns a sequence number n to the request. The timestamp is used to ensure that each client request is executed only once and a faulty client behavior does not affect other clients' requests. When an agreement replica j learns of the sequence number n committed to Q, it sends a commit message C to all execution replicas.

Let E represent the set of replicas in the execution cluster where $|E| = f + 1$ during fail-free periods. When an execution replica i receives $2g + 1$ valid and matching commit messages from A, in the form of a commit certificate $\{C_i\}$, $i \in A|2g + 1$, and if it has already processed all the requests with lower sequence than n, it produces a reply R and sends it to the client. The execution cluster also generates an execution report ER for the agreement cluster.

During normal execution, the response certificate $\{R_i\}$, $i \in E|f + 1$ obtained by the client matches replies from all $f + 1$ execution nodes. To avoid unnecessary wake-ups due to a partially faulty execution replica that replies correctly to the agreement cluster but delivers a wrong response to the client, ZZ introduces an additional check as follows: When the replies are not matching, the client resends the same request to the agreement cluster. The agreement cluster sends a reply affirmation RA to the client if it has $f + 1$ valid responses for the retransmitted request. In this context, the client accepts the reply if it receives $g + 1$ messages containing a response digest $\overline{R}$ that matches one of the replies already received. Finally, if the agreement cluster does not generate an affirmation for the client, additional nodes are started.

ZZ uses periodic checkpoints to update the state of newly commissioned replicas and to perform garbage collection on a replica's logs. Execution nodes create checkpoints of the application state and reply logs, generate a checkpoint proof CP, and send it all execution and agreement nodes. The checkpoint proof is in the form of a digest that allows recovering nodes in identifying the checkpoint data they obtain from potentially faulty nodes, and the checkpoint certificate $\{CP_i\}$, $i \in E|f + 1$ is a set of $f + 1$ CP messages with matching digests.

Fault detection in the execution replicas is based on timeouts. Both lower and higher values of timeouts may impact the system's performance. The lower may falsely detect failures, and the higher may provide a window to the faulty replicas to degrade the system's performance. To set appropriate timeouts, ZZ suggests the following procedure: The agreement replica sets the timeout τ_n to Kt_1 upon receiving the first response to the request with sequence number n; t_1 is the response time and K is a preconfigured variance bound. Based on this trivial theory, ZZ proves that a replica faulty with a given probability p can inflate average response time by a factor of:

$$\max\left(1, \sum_{0 \le m \le f} P(m)I(m)\right)$$

where:

$$P(m) = \binom{f}{m} p^m (1-p)^{f-m}$$

$$I(m) = max\left(1, \frac{K.E[MIN_{f+1-m}]}{E[MAX_{f+1}]}\right)$$

$P(m)$ represents the probability of m simultaneous failures, and $I(m)$ is the response time inflation that m faulty nodes can inflict. Assuming identically distributed response times for a given distribution, $E[MIN_{f+1-m}]$ is the expected minimum time for a set of $f + 1 - m$ replicas, and $E[MAX_{f+1}]$ is the expected maximum response time of all $f + 1$ replicas [23]. Replication costs vary from $f + 1$ to $2f + 1$, depending on the probability of replicas being faulty p and the likelihood of false timeouts π_1. Formally, the expected replication cost is less than $(1 + r)$ $f + 1$, where $r = 1 - (1 - p)^{f+1} + (1 - p)^{f+1}\pi_1$. Therefore, virtualization technology can be effectively used to realize byzantine fault tolerance mechanisms at a significantly lower resource consumption costs.

7. FAULT TOLERANCE AS A SERVICE IN CLOUD COMPUTING

The drawback of the solutions discussed earlier is that the user must either tailor its application using a specific protocol (ZZ) by taking into account the system architecture details, or require the service provider to implement a solution for its applications (Remus). Note that the (i) fault tolerance properties of the application remain constant throughout its life cycle using this methodology and (ii) users may not have all the architectural details of the

service provider's system. However, the availability of a pool of fault tolerance mechanisms that provide transparency and generality can allow realization of the notion of fault tolerance as a service. The latter perspective on fault tolerance intuitively provides immense benefits.

As a motivating example, consider a user that offers a Web-based e-commerce service to its customers that allows them to pay their bills and manage fund transfers over the Internet. The user implements the e-commerce service as a multitier application that uses the storage service of the service provider to store and retrieve its customer data, and compute service to process its operations and respond to customer queries. In this context, a failure in the service provider's system can impact the reliability and availability of the e-commerce service. The implications of storage server failure may be much higher than a failure in one of the compute nodes. This implies that each tier of the e-commerce application must possess different levels of fault tolerance, and the reliability and availability goals may change over time based on the business demands. Using traditional methods, fault tolerance properties of the e-commerce application remains constant throughout its life cycle, and hence, in the user's perspective, it is complementary to engage with a third party (the fault tolerance service provider—ftSP), specify its requirements based on the business needs, and transparently possess desired fault tolerance properties without studying the low-level fault tolerance mechanisms.

The ftSP must realize a range of fault tolerance techniques as individual modules (separate agreement and execution protocols, and heartbeat-based fault detection technique as an independent module) to benefit from the economies of scale. For example, since the failure detection techniques in Remus and ZZ are based on the same principle, instead of integrating the liveness requests within the checkpointing stream, the heartbeat test module can be reused in both solutions. However, realization of this notion requires a technique for selecting appropriate fault tolerance mechanisms based on users' requirements and a general-purpose framework that can integrate with the cloud computing environment. Without such a framework, individual applications must implement its own solution, resulting in a highly complex system environment. Further in this section, we present a solution that supports ftSP to realize its service effectively.

In order to abstract low-level system procedures from the users, a new dimension to fault tolerance is presented in [26] wherein applications deployed in the VM instances in a cloud computing environment can obtain desired fault tolerance properties from a third party as a service. The new dimension realizes a range of fault tolerance mechanisms that can transparently function on user's applications as independent modules, and a set of metadata is associated with each module to characterize its fault tolerance properties. The metadata is used to select appropriate mechanisms based on users' requirements. A complete fault tolerance solution is then composed using selected fault tolerance modules and delivered to the user's application.

Consider ft_unit to be the fundamental module that applies a coherent fault tolerance mechanism, in a transparent manner, to a recurrent system failure at the granularity of a VM instance. An ft_unit handles the impact of hardware failures by applying fault tolerance mechanisms at the virtualization layer rather than the user's application. Examples of ft_units include the replication scheme for the e-commerce application that uses a checkpointing technique such as Remus (ft_unit1), and the node failures detection technique using the heartbeat test (ft_sol2). Assuming that the ftSP realizes a range of fault tolerance mechanisms as ft_units, a two-stage delivery scheme that can deliver fault tolerance as a service is as follows:

The *design stage* starts when a user requests the ftSP to deliver a solution with a given set of fault tolerance properties to its application. Each ft_unit provides a unique set of properties; the ftSP banks on this observation and defines the fault tolerance property p corresponding to each ft_unit as $p=(u,\hat{p},A)$, where u represents the ft_unit, $\hat{p}$ denotes the high-level abstract properties such as reliability and availability, and A denotes the set of functional, structural, and operational attributes that characterize the ft_unit u. The set A sufficiently refers to the granularity at which the ft_unit can handle failures, its limitations and advantages, resource consumption costs, and quality of service parameters. Each attribute $a \in A$ takes a value $v(a)$ from a domain D_a, and a partial (or total) ordered relationship is defined on the domain D_a. The values for the abstract properties are derived using the notion of fault trees and the Markov model as described for the availability property in Table 7.1. An example of fault tolerance property for the ft_unit u_1 is $p=(u_1, \hat{p}=\{reliability = 98.9\%,\ availability = 99.95\%\},$ $A=\{mechanism = semiactive\_replication,\ fault\_model = server\_crashes,\ power\_outage,\ number\_of\_replicas = 4\})$.

Similar to the domain of attribute values, a hierarchy of fault tolerance properties $\leq_p$ is also defined: If P is the set of properties, and given two properties p_i, $p_j \in P$, $p_i \leq_p p_j$ if $p_i \cdot p = p_j \cdot p$ and for all $a \in A$, $v_i(a) \leq v_j(a)$. This hierarchy suggests that all ft_units that hold the property p_j also satisfy the property p_i. The fault tolerance requirements of the users are assumed to be specified as desired properties p_c, and for each user request, the ftSP first generates a shortlisted set S of ft_units that match p_c. Each ft_unit within the set S is then compared, and an ordered list based on user's requirements is created. An example

of the matching, comparison, and selection process is as follows:

As an example, assume that the ftSP realizes three ft_units with properties

$p_1 = (u_1$, A = {mechanism = heartbeat_test, timeout_period = 50 ms, number_of_replicas = 3, fault_model = node_crashes})
$p_2 = (u_2$, A = {mechanism = majority_voting, fault_model = programming_errors})
$p_3 = (u_3$, A = {mechanism = heartbeat_test, timeout_period = 25 ms, number_of_replicas = 5, fault_model = node_crashes})

respectively. If the user requests fault tolerance support with a robust crash failure detection scheme, the set S = (u_1, u_3) is first generated (u_2 is not included in the set because it doesn't target server crash failures alone, and its attribute values that contribute to robustness are not defined) and finally after comparing each ft_unit within S, ftSP leverages u_3 since it is more robust than u_1.

Note that each ft_unit serves only as a single fundamental fault tolerance module. This implies that the overall solution ft_sol that must be delivered to the user's application can be obtained by combining a set of ft_units as per specific execution logic. For instance, a heartbeat test-based fault detection module must be applied only after performing replication, and the recovery mechanism must be applied after a failure is detected. In other words, ft_units must be used to realize a process that provides a complete fault tolerance solution, such as:

ft sol[
invoke:ft unit(*VM-instances replication*)
invoke:ft unit(*failure detection*)
do{
execute(*failure detection ft unit*)
}while(*no failures*)
if(*failure detected*)
invoke:ft unit(*recovery mechanism*)
]

By composing ft_sol using a set of modules on the fly, the dimension and intensity of the fault tolerance support can be changed dynamically. For example, the more robust fault detection mechanism can be replaced with a less robust one in the ft_sol based on the user's business demands. Similarly, by realizing each ft_unit as a configurable module, resource consumption costs can also be made limited. For example, a replication scheme using five replicas can be replaced with one having three replicas if desired by the user.

The *runtime stage* starts immediately after ft_sol is delivered to the user. This stage is essential to maintain a high level of service because the context of the cloud computing environment may change at runtime, resulting in mutable behavior of the attributes. To this aim, the ftSP defines a set of rules R over attributes $a \in A$ and their values $v(a)$ such that the validity of all the rules $r \in R$ establishes that the property p is supported by ft_sol (violation of a rule indicates that the property is not satisfied). Therefore, in this stage, the attribute values of each ft_sol delivered to users' applications is continuously monitored at runtime, and a corresponding set of rules are verified using a validation function $f(s, R)$. The function returns true if all the rules are satisfied; otherwise, it returns false. The matching and comparison process defined for the design stage is used to generate a new ft_sol in case of a rule violation. By continuously monitoring and updating the attribute values, note that the fault tolerance service offers support that is valid throughout the life cycle of the application (both initially during design time and runtime).

As an example, for a comprehensive fault tolerance solution ft_sol s_1 with property

$p_1 =$ (s_1, $\hat{p}$ = {reliability = 98.9%, availability = 99.95%}, A = {mechanism = active_replication, fault_detection = heartbeat_test, number_of_replicas = 4, recovery_time = 25 ms}), a set of rules R that can sufficiently test the validity of p_1 can be defined as:

r_1: number_of_server_instances ≥ 3
r_2: heartbeat_frequency = 5 ms
r_3: recovery_time ≤ 25 ms

These rules ensure that end reliability and availability are always greater than or equal to 98.9 percent and 99.95 percent, respectively.

A conceptual architectural framework, the *Fault Tolerance Manager* (FTM), provides the basis to realize the design stage and runtime stage of the delivery scheme, and serves as the basis for offering fault tolerance as a service (see Figure 7.5). FTM is inserted as a dedicated service layer between the physical hardware and user applications along the virtualization layer. FTM is built using the principles of service-oriented architectures, where each ft_unit is realized as an individual Web service and ft_sol is created by orchestrating a set of ft_units (Web services) using the business process execution language (BPEL) constructs. This allows the ftSP to satisfy its scalability and interoperability goals. The central computing component, denoted as the FTMKernel, has three main components:

- *Service Directory*: It is the registry of all ft_units realized by the service provider in the form of Web services that (i) describes its operations and input/output data structures (WSDL and WSCL), and(ii) allows other ft_units to coordinate and assemble with it. This component also registers the metadata representing the fault tolerance property of each ft_unit. Service

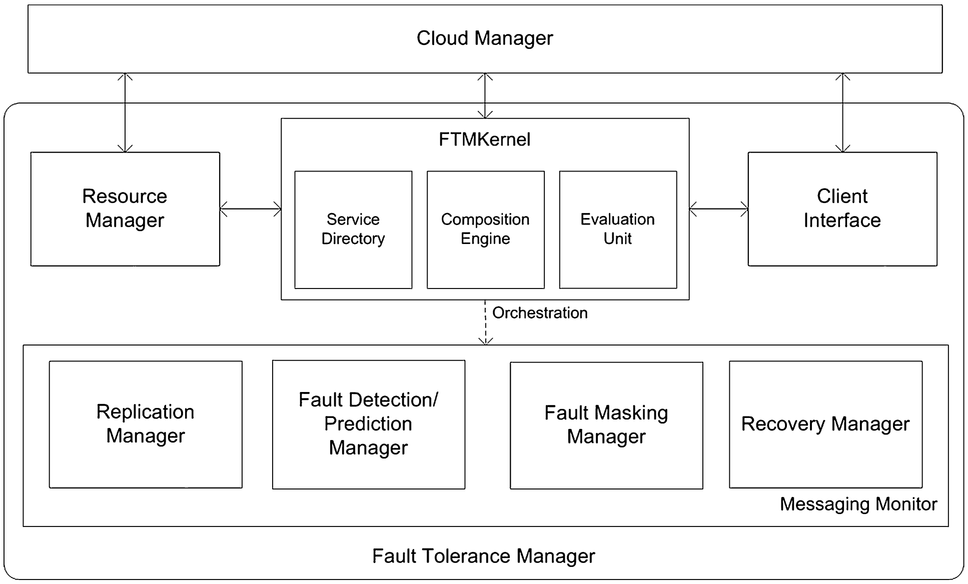

FIGURE 7.5 Architecture of the fault tolerance manager showing all the components.

Directory matches user's preferences and generates the set S of ft_units that satisfy p_c.

- *Composition Engine*: It receives an ordered set of ft_units from the service directory as input and generates a comprehensive fault tolerance solution ft_sol as output. In terms of service-oriented architectures, the composition engine is a Web service orchestration engine that exploits BPEL constructs to build a fault tolerance solution.
- *Evaluation Unit*: It monitors the composed fault tolerance solutions at runtime using the validation function and the set of rules defined corresponding to each ft_sol. The interface exposed by Web services (WSDL and WSCL) allows the evaluation unit to validate the rules. If a violation is detected, the evaluation unit updates the present attribute values in the metadata; otherwise, the service continues uninterrupted.

Finally, let's take a brief look at a set of components that provide complementary support to fault tolerance mechanisms that are included in the FTM. These components affect the quality of service and support ftSP in satisfying user's requirements and constraints (see checklist: "An Agenda for Action for Satisfying Users' Requirements and Constraints Activities").

For example, consider that at the start of the service, the resource manager generates a profile of all computing resources in the cloud and identifies five processing nodes $\{n_1, \ldots, n_5\} \in N$ with the network topology represented in Figure 7.6a. Further, consider that the FTMKernel, upon gathering the user's requirements from the Client Interface, chooses a passive replication mechanism for the e-commerce service. Based on the chosen fault tolerance mechanism (the set of ft_units that realize the

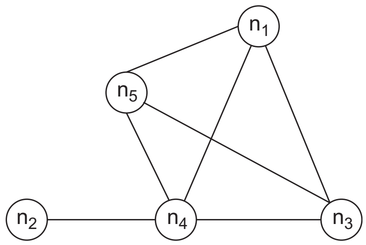

FIGURE 7.6A Resource graph.

envisioned passive replication scheme), FTMKernel requires that the following conditions be satisfied: (i) the replica group must contain one primary and two backup nodes, (ii) the node on which the primary replica executes must not be shared with any other VM instances, (iii) all the replicas must be located on different nodes at all times, and (iv) node n_5 must not allow any user-level VM instance (rather, it should be used only to run system-level services such as monitoring unit). An overview of the activities performed by each supporting component in the FTM is as follows:

- The replication manager (RM) selects the node n_1 for the primary replica and nodes n_3 and n_4, respectively, for two backup replicas so that a replica group can be formed (see Figure 7.6b). Assume that the replication manager synchronizes the state between the replicas by frequently checkpointing the primary and updating the state of backup replicas.
- The messaging manager establishes the infrastructure required for carrying out the checkpointing protocol and forms the replica group for the e-commerce service (see Figure 7.6c).

An Agenda for Action for Satisfying Users' Requirements and Constraints Activities

Figure 7.5 illustrates the overall architecture of the Fault Tolerance Manager (FTM). Satisfying the user's requirements and constraints on the functionality of each component is as follows (check all tasks completed):

_____**1.** *Client Interface*: This component provides a specification language, which allows clients to specify and define their requirements.

_____**2.** *Resource Manager*: This component maintains a consistent view of all computing resources in the cloud to:

_____**(i)** Efficiently perform resource allocation during each user request.

_____**(ii)** Avoid over provisioning during failures.

The resource manager monitors the working state of physical and virtual resources, maintains a database of inventory and log information, and a graph representing the topology and working state of all the resources in the cloud.

_____**3.** *Replication Manager*: This component supports the replication mechanisms by invoking the replicas and managing their execution as defined in the ft_unit. The set of replicas that are controlled by a single replication mechanism is denoted as a replica group. The task of the replication manager is to make the user perceive a replica group as a single service and to ensure that each replica exhibits correct behavior in the fail-free periods.

_____**4.** *Fault Detection/Prediction Manager*: This component provides FTM with failure detection support at two different levels. The first level offers failure detection globally, to all the nodes in the cloud (infrastructure-centric), and the second level provides support only to detect failures among individual replicas in each replica group (user application-centric). This component supports several well-known failure detection algorithms (gossip-based protocols, heartbeat protocol) that are configured at runtime according to user's preferences. When a failure is detected in a replica, a notification is sent to the fault masking manager and recovery manager.

_____**5.** *Fault Masking Manager*: The goal of this component is to support ft_units that realize fault masking mechanisms so that the occurrence of faults in the system can be hidden from users. This component applies masking procedures immediately after a failure is detected so as to prevent faults from resulting into errors.

_____**6.** *Recovery Manager*: The goal of this component is to achieve system-level resilience by minimizing the downtime of the system during failures. It supports ft_units that realize recovery mechanisms so that an error-prone node can be resumed back to a normal operational mode. The support offered by this component is complementary to that of the failure detection/prediction manager and fault masking manager, when an error is detected in the system. FTM maximizes the lifetime of the cloud infrastructure by continuously checking for occurrence of faults and by recovering from failures.

_____**7.** *Messaging monitor*: This component extends through all the components of FTM and offers the communication infrastructure in two different forms: message exchange within a replica group and intercomponent communication within the framework. The messaging monitor integrates WS-RM standard with other application protocols to ensure correct messaging infrastructure even in the presence of failures. This component is therefore critical in providing maximum interoperability and serves as a key QoS factor.

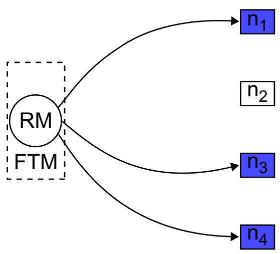

FIGURE 7.6B Nodes selected by replication manager.

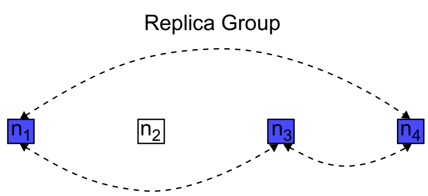

FIGURE 7.6C Messaging Infrastructure created (forms a replica group).

- Assume that the service directory selects a proactive fault tolerance mechanism. As a consequence, the failure detection/prediction manager continuously gathers the state information of nodes n_1, n_3, and n_4, and verifies if all system parameter values satisfy threshold values (physical memory usage of a node allocated to a VM instance must be less than 70 percent of its total capacity).
- When the failure detection/prediction manager predicts a failure in node n_1 (see Figure 7.6d), it invokes the fault masking ft_unit that performs a live migration of the VM instance. The entire OS at node n_1 is

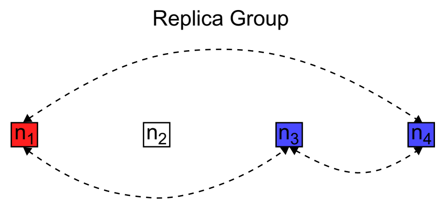

FIGURE 7.6D Failure detected at node n_1.

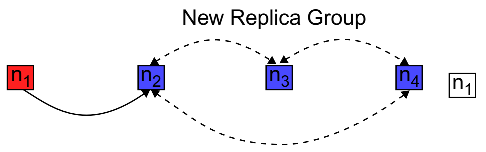

FIGURE 7.6E Fault masking performed – VM instance migrated to node n_2.

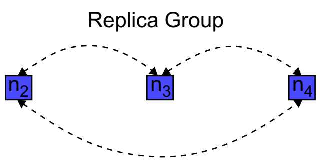

FIGURE 7.6F Recovery Manager brings back node n_1 to working state.

moved to another location (node n_2) so that e-commerce customers do not experience any impact of the failure.

- Although the high availability goals are satisfied using the fault masking manager (see Figure 7.6e), the IaaS may be affected since the system now consists of four working nodes only. Therefore, FTM applies robust recovery mechanisms at node n_1 to resume it to a normal working state, increasing the system's overall lifetime (see Figure 7.6f).

Within the FTM framework, the notion of providing fault tolerance as a service can therefore be effectively realized for the cloud computing environment. Based on FTM's delivery scheme, users can achieve high levels of reliability and availability for their applications without having any knowledge about the low-level mechanisms, and dynamically change the fault tolerance properties of its applications (based on the business needs) at runtime.

8. SUMMARY

Fault tolerance and resilience in cloud computing are critical to ensure correct and continuous system operation. We discussed the failure characteristics of typical cloud-based services and analyzed the impact of each failure type on user's applications. Since failures in the cloud computing environment arise mainly due to crash faults and byzantine faults, we discussed two fault tolerance solutions, each corresponding to one of these two classes of faults. The choice of the fault tolerance solutions was also driven by the large set of additional properties that they offer (generality, agility, transparency, and reduced resource consumption costs).

We also presented an innovative delivery scheme that leverages existing solutions and their properties to deliver high levels of fault tolerance based on a given set of desired properties. The delivery scheme was supported by a conceptual framework, which realized the notion of offering fault tolerance as a service to user's applications. Due to the complex nature of cloud computing architecture and difficulties in realizing fault tolerance using traditional methods, we advocate fault tolerance as a service to be an effective alternative to address users' reliability and availability concerns.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Crash faults do not cause the system components to completely stop functioning or remain inactive during failures (power outage, hard disk crash).
2. True or False? Byzantine faults do not lead the system components to behave arbitrarily or maliciously during failure, causing the system to behave unpredictably incorrect.
3. True or False? The system is rarely monitored at runtime to validate, verify, and ensure that correct system specifications are being met.
4. True or False? The system state is captured and saved based on undefined parameters (after every 1024 instructions or every 60 seconds).
5. True or False? Critical system components are duplicated using additional hardware, software, and network resources in such a way that a copy of the critical components is available even before a failure happens.

Multiple Choice

1. What measures the strength of the fault tolerance mechanism in terms of the granularity at which it can handle errors and failures in the system:
   A. Resource consumption
   B. Performance

C. Fault tolerance model
D. Multiple machines within the same cluster
E. All of the above

2. What factor deals with the impact of the fault tolerance procedure on the end-to-end quality of service (QoS) both during failure and failure-free periods?
A. Resource consumption
B. Fault tolerance model
C. Performance
D. Multiple machines within the same cluster
E. All of the above

3. How many replicas of an application can be placed on the hosts that are connected by a ToR switch (within a LAN)?
A. One
B. Three
C. Five
D. Four
E. Two

4. How many replicas of an application can be placed on the hosts belonging to different clusters in the same data center (on the hosts that are connected via a ToR switch and AggS)?
A. One
B. Three
C. Five
D. Four
E. Two

5. How many replicas of an application can be placed on the hosts belonging to different data centers (connected via a switch), AggS and AccR?
A. Two
B. Four
C. One
D. Three
E. Five

Chapter 8

Securing Web Applications, Services, and Servers

Gerald Beuchelt
The MITRE Corporation[1], *Bedford, MA, U.S.A.*

1. SETTING THE STAGE

The development of a distributed hypertext system in the early 1990s at the CERN in Switzerland was one of the defining moments in making the Internet available to an audience beyond academia and specialized communities. The combination of a simple, yet powerful, transport protocol—HTTP—with a specialization of the Standard Generic Markup Language (SGML) made it possible to render complex content on the fly and link related information, even if it was distributed.

As with many other information systems technologies, the early implementation of the Web included only very limited built-in security, especially since the system was initially designed for use within a research facility. However, the growth of the hypertext system at CERN into the World Wide Web required much more advanced security controls.

Defining Threats to Your Web Assets

Initially, there were only very few real threats to the WWW: early on, hackers proved their ability and highlighted potential threats to the new environment by defacing Web sites. Once commercial transactions (such as online shopping) and other high-value information exchanges were starting to use the Web, the number of potential threat actors and threats grew quickly. Today, any public or private Web application or service operator will need to perform at least a cursory threat and vulnerability assessment to determine appropriate risk mitigation strategy for their Web assets.

Depending on the use cases, the data, and the audience of a Web asset, a variety of threat actors should be considered when performing a threat assessment. Among these threat actors one may find a diverse crowd: script kiddies, disgruntled employees, organized crime, hacktivists, terrorists, or foreign intelligence agencies. While their capabilities and credibility as threat actors may vary significantly, they are all credible sources of attacks against simple Web sites such as nonprofit club home pages, or highly secured commercial targets such as banks or e-commerce sites.

While Web assets are typically more accessible than other services (such as file servers or databases), the general approach to performing risk assessment and management is very similar. One useful approach is described in the Special Publication (SP) series of the National Institute for Standards and Technologies (NIST) of the United States. Specifically, SP 800-30 rev. 1 and SP 800-39 describe a comprehensive approach to ensuring threat and risk assessment and mitigation. The reader is strongly encouraged to review these documents for further guidance on implementing their own risk management strategy.

Surveying the Legal Landscape and Privacy Issues

In addition to the embarrassment and potential liability for monetary damage to third parties after exposure to hackers, Web operators are often also subject to other regulatory requirements. For example, Web sites that store or process personally identifiable information (PII) may be required to disclose their data handling policies, and may have to restrict access for young children. The legal requirements for Web site operators vary from country to country, and lack of clearly defined "borders" on the Internet may require compliance with differing, sometimes contradictory, regulatory regimes.

All Web operators will minimally need to comply with the terms of service of their service provider and the laws applying to them. For example, U.S.-based providers

1. The opinions and guidance presented here are those of the author and do not necessarily reflect the positions of The MITRE Corporation, its customers or sponsors, or any part of the U.S. federal government.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00008-8

will need to review their Web sites in the light of very diverse laws, including (but not limited to) the Children's Online Privacy Protection Act (COPPA), Sarbanes-Oxley Act (SOX), Health Insurance Portability and Accountability Act (HIPAA), and the Privacy Act. European operators will need to address not only the requirements of their respective local countries, but also the European Union Data Protection Directive.

In general, any Web site operator handling information from their employees or customers, visitors, or third parties is well advised to consult with a local law firm that specializes in Internet, compliance, and privacy law.

Web Services Overview

Web services have become a widely used technology in both corporate and Internet applications. IT practitioners such as architects, developers, and administrators have been moving away from traditional client-server architectures to loosely coupled service environments to a number of issues. Service architectures rely on clearly defined interfaces so that service clients and service providers can change their internal architectures independently from each other, allowing decoupling the development processes for different systems components. This process started in the late 1980s and has been implemented in specialized distributed architectures such as CORBA, COM+, or Java RMI. The success of Web technologies in the mid-1990s inspired system architects to profile these new platform agnostic technologies to build distributed systems that can interoperate across vendors and runtime architectures. Web services have been defined in different ways; in this chapter we will focus on the following two principal realizations of distributed services that typically use the Hyper Text Transfer Protocol (HTTP) for exchanging information:

- SOAP Web services were popularized in the early 2000s by Microsoft and IBM, and have seen broad adoption across very different platforms. SOAP services are built around the concept of a SOAP envelope, an XML document that contains a SOAP header, and a SOAP body. The header defines the necessary metadata for the SOAP message, including processing instructions and security elements. The SOAP body can—in principal—transport any media type, although the core protocol was originally formulated around XML documents.
- HTTP services have been in use since the early days of the worldwide Web. The original design of the HTTP protocol included not only the well-known operations such as GET (to retrieve data) or POST (to modify data), which are commonly used by Web browsers, but also PUT (to create data) and DELETE (to delete data). In addition, HTTP also supports other operations that allow comprehensive management of the service and the interaction. Roy Fielding formalized the common best practices around creating HTTP services in his dissertation and coined the term *Representational State Transfer (REST)* to describe the architectural style of well-designed HTTP systems.

The protocols, architecture, and design of Web services alone are fairly complex. The reader is expected to have a basic understanding of how HTTP and SOAP work, how they are currently being used, and how they can be created. The goals of this chapter are to provide a general overview of the breadth of Web service security, give an introduction to the subject area, and guide the reader to sources with deeper information.

This chapter addresses both REST HTTP service and SOAP-based Web services. Each technology has its strengths and weaknesses, and users should clearly enumerate the requirements they have for their Web service environment before deciding to implement one or the other. In many complex cases, a hybrid environment will prove to be the best approach (See Sidebar: Protocol Versions).

Protocol Versions

Within this chapter, we will always reference the latest versions of the protocols referenced. Some of the protocols are backward compatible, since they only add features to the overall specification, but in many instances the protocols break backward compatibility to fix significant security holes. Existing implementations of these security protocols sometimes lag behind the latest standardized version (TLS being one example), but increasingly the standards community works in a much more agile way, where implementation of draft specifications are available and fully supported by vendors (OAuth 2.0 or higher). Depending on the application of Web services, the user will need to make a business-requirements and risk-based determination of which version of the protocol should be used.

2. BASIC SECURITY FOR HTTP APPLICATIONS AND SERVICES

Since HTTP services implementing a REST architectural style (often called REST Services) are simply using the HTTP stack, all security aspects of HTTP apply. At the same time, there is a critical distinction to Web applications: For the latter, the user agent (the software making the HTTP requests) is a Web browser, which is event-driven and operated by a human. Operations such as providing username and password credentials, selecting PKI certificates, or making choices about how to interact with

the Web server are not complicated for the client. This is all very different if the client user is an agent.

Basic authentication and some other authentication and authorization mechanisms are built into the HTTP stack and the layered protocols supported by most operating systems and clients. At the same time, many of these security mechanisms were created to support end-user facing agents such as Web browsers, and they often require considerable human interaction in order to work as designed. For example, HTTP Basic Authentication or HTML forms-based authentication with clear text passwords works well for an end user that needs to access a Web site (or Web application), but username/password tokens are less ideal for machine-to-machine interactions, since they (i) require a secure store of the secret, but (ii) do not offer a particularly high level of security.

This part of the chapter introduces a number of widely available and deployed HTTP mechanisms that may be used to build interoperable, secure machine-to-machine HTTP services. In general, most security mechanism supported by the HTTP specification itself are typically the most interoperable, while layered protocols and mechanisms (such as those provided by the GSS-API and SASL) tend to be less interoperable out of the box.

Basic Authentication

HTTP[2] provides Basic Authentication[3] as part of the standard HTTP stack, where the exchange of the credential is performed. For typical Web applications, the server denies access to the resources that was requested at the URI, and returns an HTTP status code of 401, including a WWW-Authenticate header, which needs to be set to the "Basic" authentication mechanism. The client then responds with another request to the same resource, but adds a WWW-Authorization header with the Base 64 encoding of the username and password. The server can then decode the username and password and verify the credential. While this authentication mechanism is straightforward and very easy to implement, it is of limited use in environments where HTTP is used for the following machine-to-machine communication:

1. This mechanism transmits the username and password unencrypted. The simple Base64 encoding can be decoded by anyone and must be treated as clear text. As such, this authentication mechanism can only be used in conjunction with a channel protection mechanism (such as TLS) that provides for the confidentiality of the channel.
2. Assigning username/password accounts to machines tends to lead to bad code. Often, developers will hard-code the credential into the code, making changes much harder. Even if a configuration file is used, the username and password are very often not cryptographically protected on disk.

Overall it is not recommended that one rely on username/password credentials (HTTP Basic Authentication) when implementing HTTP services, especially in production environments. Note that other browser-centric authentication mechanisms (such as HTML forms-based authentication) are not usable for client-server authentication in REST architectures.

Transport Layer Security

Transport Layer Security (TLS)[4] is based on the Secure Socket Layer (SSL) protocol that was developed in the 1990s by the Netscape Corporation. The basic design requires a X.503 V3-based Public Key Infrastructure (PKI) at least for the server and requires client and server to maintain a session state. Both use PKI to negotiate a session master key: This approach ensures that the asymmetric cryptography is used to introduce client and server and establish a secure channel between the two communication partners. The establishment of the secure session key using symmetric cryptography allows leveraging the efficiency of these mechanisms in bulk encryption transactions. While most clients and servers today still support SSL 3.0 and TLS 1.0, a move to TLS 1.1 is recommended to avoid potential security holes.

Server Authentication

Every TLS transaction requires the server to authenticate itself to the client. This is typically initiated by the client sending the server a list of supported TLS versions, supported cipher-suites, and other connection information (such as the time or random parameters). Note that this initial request typically requires the client to connect to a port different from the usual port for the protocol. For example, HTTP usually operates on TCP port 80, but the TLS/SSL version of HTTP (called HTTPS) is defined to operate on port 443. The server responds with a list including the same information and also the server PKI certificate. The subject identifier of the certificate is the Web address of the server (such as https://www.example.com). The client can then use the server certificate to authenticate the server, and responds with a message that

2. RFC 2616, "Hyper Text Transfer Protocol—HTTP 1.1," R. Fielding et al., Internet Engineering Task Force, June 1999.
3. RFC 2617, "HTTP Authentication: Basic and Digest Authentication," J. Franks et al., Internet Engineering Task Force, June 1999.
4. RFC 5246, "The Transport Layer Security (TLS) Protocol Version 1.2," T. Dierks et al., Internet Engineering Task Force, August 2008.

includes a master secret, which is used to generate the session keys. Once the keys are available, the TLS handshake completes, with the client and the server starting to use the session keys and shifting to an encrypted communication channel.

Mutual Authentication

Mutual authentication means that both client and server are authenticated to each other; that is, the client needs to authenticate to the server as well. This is achieved by the server sending a Certificate Request message to the client as part of the handshake. The client will then provide a user certificate to the server. This establishes the identity of the client to the server. While subject identifiers in client certificates can vary, most often they are bound to the user's email address.

Application to REST Services

TLS channel protection adds a number of security features to the communication between a REST client and service, as follows:

1. Server authentication using strong cryptographic methods. The server certificate is bound to the server's DNS name itself by the subject identifier, thus providing additional protection against DNS attacks.
2. Channel protection. Once the secure channel handshake is complete, the secure channel provides confidentiality to the communication path between client and server. This allows the exchanges of sensitive information, including additional authentication and authorization data.
3. REST client libraries can usually make use of operating or runtime systems certificate stores in a very efficient way. Certificate stores typically provide built-in protections of the cryptographic material. Additionally, both client and server systems usually allow fairly simple updates of the certificates when needed.
4. TLS can provide a Message Authentication Code (MAC) for each packet, allowing full integrity protection of the connection.

The only significant drawback of using simple or client-authenticated TLS is the high cost of using a PKI: For cross-enterprise transactions, PKI certificates must be obtained through common trust anchors that may be too expensive in low-value transactions (such as social network interactions). For intra-enterprise connections, a custom PKI may be used, but the cost of maintaining this can also be substantial, especially for large enterprises.

GSS-API Negotiated Security

Another way to perform authentication for HTTP-based service and application is through use of the GSS-API and its security mechanisms. The GSS-API has been defined for C and the Java runtime[5] and provides a number of standard features:

- Authentication of client-server relationship through a complete handshake protocol between client and server.
- Confidentiality and integrity for the payload of the connection, independent of the protocols encapsulated. This is achieved by wrapping the payload within the structure needed for the GSS-API protected traffic. Note that the capabilities of this feature are strongly dependent on the underlying security mechanism.
- Extensibility and mechanism negotiation through the SPNego pseudomechanism. Microsoft uses this to integrate Kerberos with the HTTP protocol for authentication and provide a smooth browsing experience.

The preceding technology was initially developed in the early 1990s and has a high level of implementation maturity. At the same time, it is very focused on traditional client-server environments and encourages a much stronger coupling of the participants than is desired for typical Web services. For example, when using Kerberos over SPNego as the underlying security mechanism, the administrator will need to ensure that either client and server are part of the same Kerberos realm or there is an established trust relationship between the two realms. Since this trust and deployment model does not scale to cross-organizational deployments, this approach can only be used effectively within a single administrative domain.

3. BASIC SECURITY FOR SOAP SERVICES

The situation for SOAP-based Web services (see Sidebar: SOAP-based Web Services) is significantly different from basic HTTP services: While SOAP may use the HTTP protocol for transport, it was designed to be transport independent, and as such it needs to re-create the entire security stack in a self-contained way. This is achieved by extending the SOAP headers to support security-related information in the WS-Security protocol, and other profiles and protocols that build on top of it.

5. The C binding is defined in the IETF RFC 2744, and the Java binding is standardized in JSR-72. See http://tools.ietf.org/html/rfc2744 and http://jcp.org/aboutJava/communityprocess/review/jsr072/index.html for more information.

SOAP-based Web Services

SOAP version 1.2[6] or higher is a flexible XML-based protocol to exchange information. Originally developed by Microsoft, IBM, and others, SOAP is available today on most Web-enabled platforms. Conceptually, SOAP defines an Envelope as the root node of the XML document. The Envelope contains two child elements: the Header and the Body of the SOAP message. The Body typically contains the main payload of the message, which is intended to be an XML-serialized representation of a data model. The Header section of the Envelope may contain metadata about the message, sender and receiver, and about the transaction itself. The Header is highly customizable and extensible.

SOAP was originally developed as a Web service protocol, with an HTTP transport binding. At the same time, the designers of the protocol made sure that the SOAP specification was not dependent on any features of the underlying transport. As a result, SOAP can be used over a large number of transport protocols today, thus providing a consistent way of creating services over a number of different platforms. Such platforms include SMTP, FTP, and message queuing protocols. This flexibility does not come for free though, since many transport semantics (such as session security, routing, and acknowledgments that are provided by the underlying transport protocols need to be replicated within the SOAP stack. This can lead to significant performance issues and replication of functionality at different layers.

For this chapter, it is assumed that the reader has a good understanding of the basic SOAP protocol structures.

WS-Security Overview

WS-Security[7] (often abbreviated WSS) defines a Header extension to provide a number of features for SOAP-based messages, as follows:

- Signing the message to provide integrity protection and nonrepudiation
- Encrypting the message to provide message-level confidentiality
- Attaching arbitrary security tokens to the messages to provide the identity of the sender

It should be noted that since WS-Security is only tied to the SOAP messaging structures, it is completely transport independent and can therefore be used over the SOAP HTTP binding, but also with any other form of SOAP transport. At the same time due to its independence, WS-Security can be combined with the security mechanisms of the underlying transport security.

6. "SOAP Version 1.2," M. Gudgin et al., W3C Recommendation, April 2007.
7. "Web Service Security: SOAP Messaging Framework 1.1," A. Nadlin et al., OASIS Open, November 2006.

To provide the various features mentioned above, WS-Security leverages the XML Encryption and Signature standards. Users of WS-Security should have a robust understanding of how these standards work, minimally from an API perspective, but ideally also from a protocol point of view. The WSS headers directly use the <Signature>, <KeyInfo>, and <EncryptedData> elements of the XML Signature and Encryption standards, repectively.

For example, a SOAP message may be signed and encrypted at the message level using WS-Security and transported over an encrypted HTTPS connection as well. For complex situations, where the SOAP message is routed by SOAP intermediaries that sit between the sender and the server, this feature can be used to provide both: (i) secure point-to-point connections between the sender, receiver, and their respective intermediaries using HTTP over TLS, and (ii) end-to-end security from the sender to the receiver using message-level encryption.

Protocol Design

As discussed, WS-Security injects a security header as an XML child node into the SOAP Header (see Figure 8.1). This security header can contain a number of different elements that enable the various features of WSS. Note that the following examples reference the usage of WS-Security with SOAP 1.2 or higher only. The WS-Security specification also defines the use of SOAP 1.1 or higher, but this will be omitted here. The namespace prefixes below are identical to the ones used in the WSS 1.1 or higher specification. For real implementations they may be different, as long as the XML namespace rules are followed.

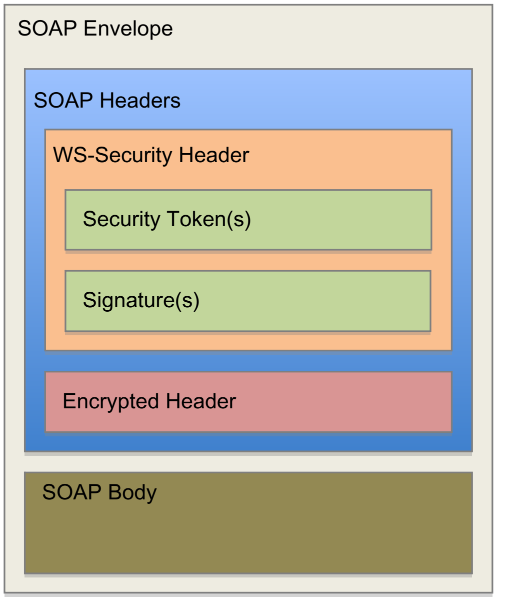

FIGURE 8.1 SOAP and WS-Security message layout.

The <wsse:Security> is the base WS-Security header element within the <S12:Header> element of the SOAP message. It may contain a number of typical attributes from the SOAP headers, such as mustUnderstand, to indicate that the receiver or intermediary must understand the WSS header in order to correctly process the SOAP message. Also, the <Security> header can be extended with any additional attribute or child element, effectively providing a very flexible extension point. It should be noted that open-ended extension points like this—while desirable to protocol implementers and vendors—may introduce significant interoperability issues when being deployed: If vendor-specific extensions are required for operation, environments that require cross-platform interoperability may run into significant difficulties.

In order to enable signature and encryption of arbitrary parts of the SOAP message, the WSS specification introduces the ability to reference nodes of the entire SOAP Envelope using the wsu:Id attribute. Similar to an anchor in an HTML page, an XML element within the message can be tagged with this attribute and then be referenced within the WSS header structures that are used for providing signature and encryption.

Signature is provided through the <ds:Signature> element that may contain the crypto material (such as a <ds:KeyInfo> element) and additional information to provide identification of the type of signer, the signature and canonicalization[8] algorithm, and references to the signed elements.

For encryption of elements, WSS differentiates between header elements that need to be encrypted and the main SOAP Body (or portions of the body). For the headers, WSS introduces the <wsse:EncryptedHeader> element that may be processed by SOAP intermediaries or the final receiver of the messages. If the SOAP handling system cannot decode the encrypted header, it needs to leave it in place. Within the SOAP body, the <xenc:EncryptedData> element is used to wrap encrypted parts of the XML infoset within the overall message structure.

In either case, the WSS header will contain the necessary key information to decrypt the data, similar to how this is handled for signatures. When decrypting, the decrypted elements replace the <xenc:EncryptedData> and <wsse:EncryptedHeader> elements, respectively.

Usage of WS-Security

By itself, WS-Security is of limited use: It describes how security elements such as tokens and signatures can be incorporated into a SOAP message. It also provides limited instructions on how to protect portions of the message using these security elements.

Authentication with WSS

A common use of WS-Security is for authentication of the incoming request. In order to process (such as an update to an account using a SOAP request), the bank service will need to verify the identity of the invoker (authentication) so that it can apply its authorization policies. For this, the clients will need to attach one or more security tokens to the WS-Security header that prove their users' identity. WS-Security provides for a number of built-in tokens such as <wsse:UsernameToken> or the more generic <wsse:BinarySecurityToken>, but it can also be extended to support other token types as well. Common stacks such as Apache Axis or .NET WCF support these and others such as SAML or vendor-specific tokens as well (see Sidebar: Attaching Policies to Web Services).

Attaching Policies to Web Services

Authentication of a single request is achieved by providing the token within the security header. Since there are countless ways of doing this, the service needs to communicate to the client the type of acceptable tokens, acceptable configurations of these tokens, and how to protect them. This is typically done by adding the WS-SecurityPolicy elements: WS-SecurityPolicy is another OASIS Open standard, available at http://docs.oasis-open.org/ws-sx/ws-securitypolicy/v1.3/os/ws-security-policy-1.3-spec-os.pdf. It can prescribe the required configuration for a number of WS-Security related parameters.

WS-Security Policy is written within the WS-Policy framework, which is for describing policies associated with a Web service. In order to make WS-Policy statements available to clients, most stacks use WS-Policy Attachments, a W3C Recommendation (available at http://www.w3.org/TR/ws-policy-attach/) that describes how WS-Policy elements map to WSDL elements.

In the easiest case, a simple UsernameToken is used, which can include the password in clear text. Obviously, such a token would typically not be used without protecting the message for confidentiality. Alternatively, a trusted authentication server could sign a UsernameToken or a SAML statement. The service could then decide to trust the authentication server and not require additional credentials. If a SAML statement is used for authentication, the SAML Token Profile for WS-Security will describe the possible configurations that the server can request from the client.

8. WSS supports both W3C XML Canonicalization and W3C Exclusive XML Canonicalization. The latter provides a better support for XML namespaces and is recommended in most situations.

WS-I Security Profile

As seen above, the configuration parameters to simply perform authentication can be very complex. While WS-SecurityPolicy is capable of describing the server's requirements, it is impossible even within a fairly rich policy framework to describe all possible parameters for the WS-Security stack. Even though placement of individual XML elements should not matter from an infoset perspective, and most crypto parameters such as algorithms are described in the core specification, tests between different vendors have shown that acceptable interoperability cannot be achieved without a very narrow profile. The WS-I organization (now a subgroup of OASIS Open) created a number of such profiles. The WS-I Basic Security Profile includes very detailed implementation guidance for WS-Security, WS-SecurityPolicy, the various token profiles (username, SAML, X.509 certificate, Kerberos), and SOAP with Attachments. While users of WS-Security are typically not expected to implement these specifications and their profiles, it is important to understand their relevance when creating cross-platform services.

Example for a WSDL for WS-Security

Figure 8.2 contains a sample WSDL[9] for a very simple SOAP Web service with a single operation. The service requires authentication using a SAML 2.0 or higher Security token using the SAML Token Profile version 1.1 or higher. Note that within this WSDL there is no directive on how to utilize the information found within the SAML token for authorization. The SAML statement will contain information that is used for authentication and authorization. How this is used by the application server runtime and the service itself depends on the application server vendor and the service developer, respectively.

4. IDENTITY MANAGEMENT AND WEB SERVICES

Background

Since Web services are intended to implement a distributed architecture, it becomes very important to manage the identities of the participating actors: Different systems implementing the services or the clients need to fully understand who they are interacting with in order to make access control decisions that are consistent with the security policies for the systems. While this has always been the case for complex systems, the loosely coupled design of Web services exacerbates this problem and requires a number of new patterns to address this issue in a reliable way. The identity management community created a number of patterns that allow not only simple authentication, but also advanced patterns including:

- *Single Sign On (SSO) using mutually trusted identity servers.* This idea is based on the SSO mechanisms used for Web applications: A user (or machine entity) authenticates once to a trusted identity server, which issues security tokens that can be used to sign into relying parties (sometimes also called service providers). This pattern decouples the process of identification and authentication itself from the use of the authentication and authorization.
- *Federations of identity providers.* In order to allow cross-organizational access to Web services, the concept of an identity federation was introduced. In this pattern the operators of two separate identity servers (such as in Company A and Company B) decide to trust each other's authentication process. This is realized by allowing a client to exchange a security token from the identity server of Company A with a security token from Company B. This allows the client to access services that trust Company B's identity server.
- *Complex, distributed authorization.* By fully decoupling the authentication process from the authorization to access a resource, Web services can allow very flexible authorization mechanisms such as Attribute Based Access Control (ABAC).

Other patterns, such as privacy preserving authentication and authorization, have also been demonstrated and implemented using Web services-based identity management technologies. While many of these patterns were pioneered for the SOAP stack, recent developments have brought most them to REST-styled HTTP services. Due to its expressiveness and top-down design, SOAP-based identity management is quite achievable. In real-world implementations, some of the performance issues of XML processing have limited the broad adoption of SOAP-based identity management technologies. The initially less feature-rich REST designs have always leveraged the efficiency of the underlying transport protocols, resulting in a much slower availability of useful patterns, but providing a much better price/performance ratio.

Security Assertion Markup Language

The Security Assertion Markup Language (SAML)[10] was created to provide a means for exchanging information

9. For readability, XML namespaces have been removed from the listing.

about authenticated entities and their attributes between a client (also called service consumer) and a service. Fundamentally, SAML defines a set of security tokens that can hold information about an entity's authentication, its attributes, or its authorization status.[11] In addition, SAML defines a request/response protocol that allows exchanging SAML security tokens in remote procedure call (RPC)-style exchanges.

The SAML protocol stack (see Figure 8.3) extends from the basic tokens and protocol to include SAML Bindings, which describe how the SAML protocol can be used with the appropriate token types over different transport mechanisms. The Bindings are then used to build profiles for different SAML system participants such as Web browser SSO clients, identity providers, or attribute providers.

11. In SAML 2.0, the authorization token has been deprecated by the XACML protocol.

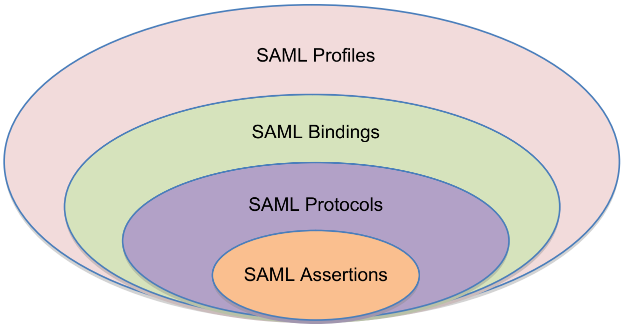

FIGURE 8.3 SAML protocol stack.

SAML Token Types

The SAML tokens are supported by many different vendors and can be used with many different protocols, even those that compete with the SAML request/response protocol. The SAML 2.0 or higher specification identifies the following three token types (called "Statements" in the specification):

- SAML Authentication Token. This statement describes how a user (or machine entity) authenticated to a given service. It can contain detailed information about the authentication act, including the time, the subject, and the authentication context.
- SAML Attribute Token. This statement can contain an arbitrary number of clear-text and encrypted attributes about a given subject, as asserted by the identity provider. This statement is the foundation for may ABAC-based authorization schemes.
- SAML Authorization Decision Token. This statement was deprecated by the XACML protocol at the time of publication of the SAML 2.0 or higher standard. It has been kept within the specification text, but should not be used unless for legacy interoperability purposes.

All tokens require a Subject element to identify the principle of the assertion. This Subject can contain identifiers (such as email addresses or distinguished names) and SubjectConfirmation elements. The use of these fields is specific to the protocols for which the tokens are used. For example, the WS-Security SAML token profile[12] defines two common SubjectConfirmation methods: Holder-of-Key (HOK) and Sender-Vouches.

Holder-of-Key ensures that the sender of the SOAP message has access to the private key of the Subject by requiring a signature over parts of the message block. This authenticates the subjects and confirms to the Web service the identity of the sender. In the Sender-Vouches method, the Web service trusts an authentication server to authenticate the client for them and requires only a signature by that authentication server over the message block.

SAML Protocol

The SAML protocol (sometimes called SAML-P to distinguish it from the SAML token format) is an XML-based protocol that implements a request/response patterns for exchanging information. It is completely transport independent and can therefore be used with a wide variety of system participants. The basic exchange implements a Request message by a client that is answered by a Response. The SAML protocol is self-contained and uses its own mechanism to indicate response status, failures, and other interaction metadata. Similar to SOAP, this independence from the underlying transport results in less effective architecture, since underlying functions such as status codes have to be replicated at the application level. The basic SAML specification defines a number of interactions, as follows:

- *SAML Assertion Query*. This protocol is used to request specific assertions about subjects from an authoritative source. This can include authentication, attribute, and authorization decision statements. The response then includes a token for the requested information about the Subject.
- *Authentication Request Protocol.* An entity can use this protocol when it wishes to obtain a statement for establishing a security context for a principal. Typically, a requester asks to obtain a SAML authentication assertion from an Identity Provider (IdP) during a Web service invocation.
- *Artifact Resolution.* A SAML Artifact is a reference to a SAML statement instead of the statement itself. This protocol is used to resolve a SAML Artifact into an actual SAML assertion.
- *Single Logout*. While Single Sign On is very desirable from a user experience perspective, single logout is critical from a security perspective. Within the SAML specification stack, this protocol ensures that assertions can be identified as invalidated once a logout was requested. It should be noted that this protocol does not guarantee logout but requires the cooperation of all relying parties.
- *Name Identifier Management and Name Identifier Mapping.* These protocols are used to create reliable, pseudonymous federations between IdPs in different administrative domains.

These protocols can then be used with different transports. The use of specific transport protocols with the SAML protocol is called a Binding and is specified in a separate document. SOAP is one of the standards transports, but other browser-centric transport bindings are

12. R. Monzillo et al., "Web Service Security: SAML Token Profile 1.1," OASIS Standard, February 2006.

available as well. The Bindings are use to define "Profiles," which describe complex function systems such as Identity Providers.

Although the SAML protocol is standardized in the core SAML specification, it is not implemented by all vendors: While SAML tokens have been popular across the entire identity management landscape, early adopters of the WS-* specifications such as IBM and Microsoft have been using these tokens with WS-Security, WS-Trust, and WS-Federation. Users will need to make sure what parts of the SAML specification stack (tokens, protocol, bindings, profiles) the vendors support.

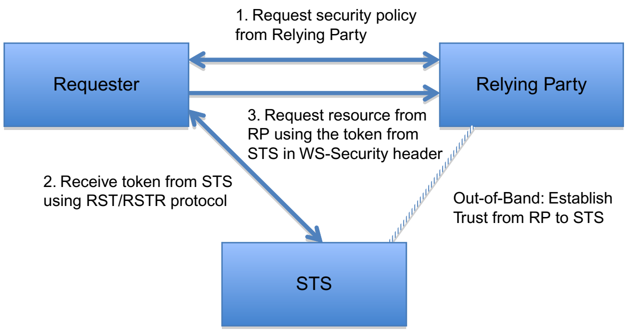

FIGURE 8.4 WS-Trust Architecture.

Using SAML Tokens with WS-*

SAML tokens have been used with other exchange protocols as well. The term *WS-* stack* commonly refers to a set of protocols that build on top of the SOAP platform and enable additional functionality for SOAP-based Web services. This includes features such as complex transactions support (WS-AtomicTransactions), reliable delivery (WS-ReliableTransport), and service discovery (UDDI). Since these features are intended to be used in a transport agnostic way, underlying features of message queuing systems cannot be relied on for guaranteed delivery, but have to be created within the SOAP envelope through SOAP header extensions.

For security, WS-Security defines the most fundamental extension, and many of the other WS-* protocols implementing security functions rely on the WS-Security framework. The use of SAML Tokens with WS-Security is standardized in the SAML Token Profile 1.1 or higher (see footnote 9).

WS-Trust Architecture

WS-Trust is an alternative to using some portions of the SAML protocol for creating an environment with a mutually trusted authentication server, a client, and a service. WS-Trust uses WS-Security for wrapping security elements such as security tokens, signatures, and encrypted data blocks.

The mutually trusted entity is in the WS-Trust environment called a Secure Token Service (STS), which responds to token requests (see Figure 8.4). At a high level, the client (called a requestor) contacts the service (called a relying party) and obtains the token requirements through the WS-SecurityPolicy of the relying party service. These requirements include the acceptable origin of the token (the STS or list of STS that are acceptable sources for tokens).

The requestor then proceeds to request such a token from a STS by sending a RequestSecurityToken (RST) message to the STS service endpoint. This request will typically include appropriate forms of authentication (from the requestor to the STS) by providing a security token within the WS-Security headers of the WS-Trust RST message.

The STS builds a token to the specification of the requestor and wraps this in the WS-Security header of the RequestSecurityTokenResponse (RSTR) message. The requestor can then proceed to interact with the relying party using the new token.

Building Federations with WS-Federation

Since WS-Trust is only used for building a distributed authorization system, OASIS has created a number of other protocols for the WS-* stack, focusing on different functionalities. One of these is the WS-Federation specification, which is used to enable the leveraging of security tokens issued by STS from different administrative domains. This means that a client can obtain a token from "their" STS and use this to access relying parties that usually trust only tokens issued by another STS. The prerequisite for this to work is setting up a federation.

It should be noted that the most significant amount of work for creating a federation is typically not the technical configuration: The process of creating and maintaining the necessary business agreement between two organizations is complex and requires collaboration with legal, financial, and potentially human resources subject matter experts.

Advanced HTTP Security

The basic security functions of HTTP described earlier are sufficient for simple client-server systems, but are hard to manage for complex multiparty interactions. In addition, the most common security transport—TLS—typically requires a comprehensive PKI roll-out, especially when using user certificates for mutual authentication.

Typical applications of HTTP applications and services in social networking or cloud environments have

use cases that cannot be easily addressed with basic HTTP authentication schemes. Furthermore, the deployment of PKI in such environments is too expensive or extremely complex: PKI implies a fairly high level of trust in the binding of the credential to a system or the user, which is hard to control in highly dynamic environments.

Based on these constraints, in 2004 a number of large Web 2.0 or higher providers (including Google, Twitter, and AOL), as well as smaller companies with deep insight into the architectures of dynamic Web applications and REST-style HTTP services, started developing technologies that are complementary to the "heavyweight" SOAP-centric identity management technologies. While initially focused on simple data sharing use cases with limited risk (such as a single sign on for blog commenting), these technologies have matured to the point where they can be used to secure commercial services and provide a simplified experience for users of social media and other Web applications.

OAuth Overview and Use Cases

The OAuth protocol dates back to the early days of social networking sites. The standard use case is for safely sharing user data held at one site with another site. This would occur when site A is a photo hosting site and site B is a site that makes prints from photos (see Figure 8.5). In this use case, users have an account at both sites and store their photos at site A. For creating a new set of prints, users will not upload or transfer their photos to site B, but instead will authorize site B to access their photo stream (or a portion thereof) on site A. This is effectively achieved by initially logging into site B and indicating the location of their photo stream (through a dropdown menu) at site A. When site B now tries to access the photo stream, the users are redirected to the login screen for site A where they need to provide their credentials. Once logged in, site A will create a token that site B can use for accessing the users' photo stream and attach this token to the HTTP redirect back to site B. The end state is now that site B has a token that it can use to attach to the HTTP request when obtaining the photos.

The exchange is somewhat more complicated than depicted in the illustration, since the Printer service initially obtains an unauthorized request token in the initial exchange between the Printer and the Photo Host service. The request token is then authorized by the user and provided to the Printer, which exchanges it into an access token. The goal for this use case is to keep the accounts at the two services separate while still allowing authorized information sharing between the two sites.

OAuth 2.0 or higher is at the time of writing in its final stages of standardization at the Internet Engineering Task Force (IETF). It is expected that the final protocol will be available very soon. Most implementations already support OAuth 2.0 or higher, and updates to implementations for transitioning from the draft versions to the final version will be minor, if any.

OpenID Connect

The original OpenID protocol was built on the concept of using URLs as identifiers for users; that is, a user would use something like "https://example.com/user" for the username. This was intended to solve the problem of discovery in identity management: Any dynamic interaction between a user and a service would only be able to leverage identity management protocols, if the relying party and the identity provider had an existing relationship. For well-defined cross-organizational interactions this is quite achievable, but to configure the respective IdPs (or

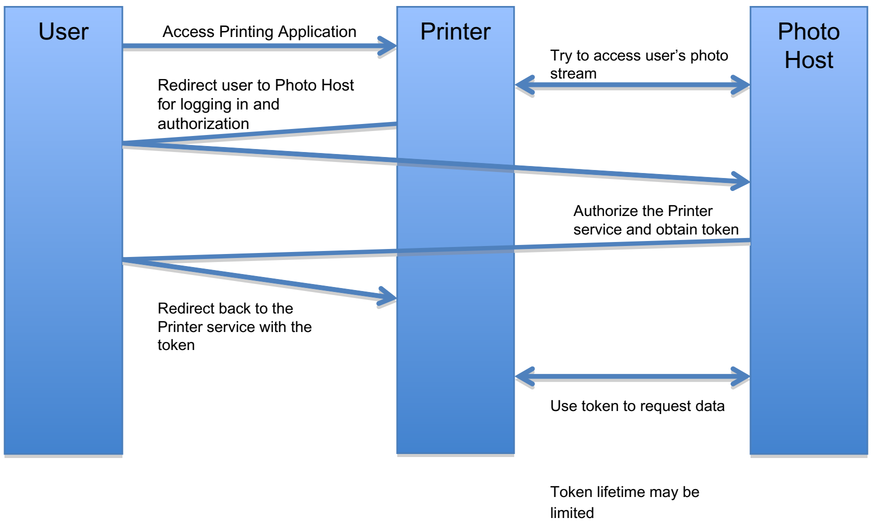

FIGURE 8.5 OAuth basic use case.

STSs), it requires relying parties and requestors to use the acceptable services for identity management and authorization services.

While the OpenID protocol did solve this problem with the URL identifier, users typically did not accept this scheme, so the large Web 2.0 or higher providers such as Google, Twitter, Facebook, and AOLsolved this by creating specialized buttons to use for OpenID login. Since most sites desired to support at least the big social networks and identity providers, the login sites often featured more than five specialized login buttons, leading to the term the *NASCAR problem*: Similar to racing cars in NASCAR, login sites would be littered with banners from all major login providers.

Additionally, the initial versions of OpenID had a number of significant security issues, leading to the realization that it would be helpful to design a new version of OpenID that could leverage a secure HTTP-based identity transport protocol. The natural choice was OAuth, and OpenID Connect now uses OAuth as its underlying security protocol. Simplified, OpenID Connect creates an identity provider Web service and uses OAuth to protect access from relying parties to it.

5. AUTHORIZATION PATTERNS

Access Control Models

Early systems implemented fairly simple access control models that rely mostly on the identity of the user and define access control lists (ACLs) that are stored with the resource that is subject to that access control list. This model has sometimes been called identity-based access control (IBAC) and has proven to be very efficient and easy to implement. Most modern operating systems support IBAC for file systems access and other security-related functions. While fast for small ACLs, very large ACLs are inefficient to evaluate, and the need to store the ACL (which is effectively a security policy for the resource) decentralized with the resources can cause significant life-cycle management problems. Some solutions such as user groups or ACL inheritance have been implemented to mitigate these shortcomings, but overall the limitations of IBAC limit its use for large-scale applications. Other access control models include role-based access control (RBAC)[13] and attribute-based access control (ABAC). Central to these models is a better separation of resources and applicable access control policies.

Web services have been pioneering technologies for implementing ABAC models especially through the introduction of the eXtensible Access Control Markup Language (XACML).[14] Since XACML was developed to complement SAML with a flexible authorization system, it shared some architectural similarities. In fact, the XACML replaces the SAML 2.0 or higher authorization decision statement with its own request response protocol.

XACML Overview

Within the XACML model, there are a number of actors that enable the distributed authorization environment. Note that some of these actors can be co-located: Certain appliances or access managers allow configurations where PEP, PDP, and PAP are c-located, as discussed in the following components:

- *Access requester (or client).* This is the entity that initiates a request.
- *Policy Enforcement Point (PEP).* The PEP intercepts the request from the client to the resources and performs an authorization check. This actor is sometimes integrated with a reverse proxy (a façade service that wraps the resource and replicates the resource's interface to the clients).
- *Policy Decision Point (PDP).* The PDP performs the actual policy evaluation, based on the information in the request from the PEP, a policy set (i.e., the merged set of applicable policies, based on policy-merging systems), configured attribute sources, and other environmental factors (such as time of day, origin or destination of request).
- *Policy Administration Point (PAP).* The policy administration point allows the configuration and administration of applicable access control policies. The PDP is configured through the PAP to use a specific set of policies.
- *Policy Information Point (PIP).* The PIP provides contextual information input into the policies, based on a request from the PDP. If the PIP provides specific attributes for identities, for example, in the form of a Directory Server, the PIP is sometimes also called an Attribute Source (AS).
- *Resource.* The resource itself provides the service for the client. While XACML is typically used for SOAP services, the resource is not required to be implemented as a SOAP service. For example, a combined PEP/service façade can be used to expose the functionality of a legacy application to SOAP-enabled clients.

13. The U.S. National Institute of Standards and Technology (NIST) has published a number of documents on RBAC and how it can be implemented. See http://csrc.nist.gov/groups/SNS/rbac/ for more information.

14. XACML is standardized at OASIS Open in the XACML Technical Committee. See here: https://www.oasis-open.org/committees/tc_home.php?wg_abbrev=xacml.

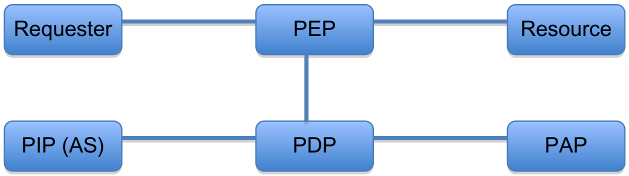

FIGURE 8.6 XACML actors overview.

The preceding components and their relation to each other are shown in Figure 8.6. Conceptually, the Requestor tries to access the Resource (typically, a SOAP-based Web service, but this is not a requirement within XACML) and is intercepted by the PEP. The PEP itself formulates a decision request to the PDP with the information that is available to it, namely, metadata from the request and the resource.

With the PDP, the applicable access policies are identified, evaluated, and—if necessary—combined into a single policy decision. Note that XACML defines a rich policy language for describing access control policies in terms of Targets, Rules, and Constraints.

The PDP responds to the PEP in a Result Response with one of the following four possible decisions: Permit, Deny, Indeterminate (no decision was possible, based on the available policies and information), or NotApplicable (the request was not applicable in this context). The response may include additional obligations that need to be abided by. The complete XACML protocol, policy language, result definition, and combination algorithms can be used for very complex situations, but it is beyond the scope of this chapter to describe the details of the XACML protocol.

XACML and SAML for ABAC and RBAC

The core XACML protocol architecture is modeled on the concepts of ABAC: attributes (either provided by an Attribute Source or other PIPs providing environmental attributes) are evaluated in the context of a specific request. Although most situations will require the identity of the requestor, ABAC can even allow pseudonymous access to resources, as long as the PDP can obtain sufficient information to arrive at a "permit" authorization decision.

The core set of XACML specifications also includes guidance on how an RBAC model can be implemented using XACML. The basic idea is to model role membership through a multivalued attribute. This attribute is then evaluated in the context of access control policies designed to reflect the role-based approach.

At the same time, the technology used to implement the access control model should not be confused with the access control model itself. This means that while XACML is currently the predominant technology to implement ABAC in distributed systems, they should not be equated.

6. SECURITY CONSIDERATIONS

Avoiding Common Errors

The flexibility of Web-based systems and the ease of implementing new services led to an early proliferation of Web applications and Web services. It became obvious pretty quickly that these new technologies resulted in a number of mistakes that were independently made by many developers. Security research groups and organizations started to look into this problem and identified a number of anti-patterns and mistakes that were particularly common, and identified measures to counter them. The following gives an overview of two well-known lists of common mistakes and useful controls, respectively.

OWASP Top 10

The OWASP Top 10 list[15] was developed by the Open Web Application Security Project (OWASP) community to enumerate common problems with Web applications. This list focuses specifically on Web application risks and deals with both transport issues (HTTP) and content problems (HTML) and how content is rendered within browsers. The latter issues are less interesting for developers of Web services, since the user agent is typically not a browser, and the data may be represented as HTML but most often is not. It is updated occasionally to reflect the changing security environment.

Figure 8.7 shows the 2010 version of the OWASP Top 10. Out of this list only A3, A4, A6, A7, A8, and A9 are highly relevant to Web service developers. Since REST-style HTTP service leverages the features of HTTP more heavily than SOAP-service using the HTTP transport binding, REST-style services will likely have to pay more attention to avoiding mistakes identified in the list. At the same time, SOAP-style services operating within standard runtime environments can suffer from issues such as security misconfigurations (A6) or problems with the transport layer protection (A9) just as easily. In the following, the more pertinent elements from the OWASP Top 10 are briefly discussed.

- A3—Broken Authentication and Session Management. If access to the HTTP resources where the service is host is not protected properly, arbitrary users may invoke the service and cause confidentiality and integrity problems. Authentication issues can arise

15. The document is available from https://www.owasp.org. The list was last updated in 2010.

A1 – Injection
A2 – Cross-Site Scripting (XSS)
A3 – Broken Authentication and Session Management
A4 – Insecure Direct Object References
A5 – Cross-Site Request Forgery (CSRF)
A6 – Security Misconfiguration
A7 – Insecure Cryptographic Storage
A8 – Failure to Restrict URL Access
A9 – Insufficient Transport Layer Protection
A10 – Unvalidated Redirects and Forwards

FIGURE 8.7 OWASP Top 10 (2010)

when the verification of accounts with the user database is compromised, user information is leaked through other channels, or the authentication session parameters are not set properly.

- A4—Insecure Direct Object References. If input of the access URL (for REST-style services) or the content of the SOAP request is not verified through input validation techniques, a malicious user may replace legitimate data references with improper data. For example, if a service call should reference Alice's account for receiving a money transfer, a malicious attacker could try to replace Alice's account number with Eve's, thus redirecting the transfer to a wrong account.
- A6—Security Misconfiguration. This can include default account, unpatched or unmaintained server code, references to old versions of services, and so on. Any security misconfiguration can be exploited by attackers to gain access, elevate privileges, or violate the confidentiality or integrity of the data.
- A7—Insecure Cryptographic Storage. Sensitive information such as personally identifiable information, financial data, user account or system security information, or any other regulated data should be encrypted, and the cryptographic keys should be properly protected.
- A8—Failure to Restrict URL Access. When URLs are accessible to users not authorized for access, attackers can exploit such holes and gain access to the service. All URLs—either those used for REST-style resources or SOAP HTTP endpoints—must be protected from unauthorized accessed and should ideally require at least one form of authentication. REST-style services can use the authentication and authorization mechanisms described earlier in the chapter; SOAP services can also use the application protocol-specific authentication mechanism.
- A9—Insufficient Transport Layer Protection. Lack of TLS protection, use of expired or revoked PKI certificates, or bad configuration leads potentially to violations of confidentiality and integrity. Both client and service should verify the validity of certificates and cancel transactions if they do not match.

SANS Top 20

The SANS Top 20 list of critical security controls[16] enumerates the most important technical and administrative controls for preventing or limiting attacks on computer systems. The list was developed by a number of experts from the U.S. government and the commercial sector and condenses a lot of best practices of good systems management. They provide not only a description of implementable countermeasures and system configurations, but also metrics to measure the effectiveness of the controls within a given environment. Additionally, the SANS Top 20 control description include references to the NIST SP 800-53[17] control set, which is mandatory for many systems operated by the U.S. federal government.

The controls themselves are very generic and not specific to Web services. At the same time, they can be applied to the architectural concepts, technologies, and deployed systems implementing Web services. The complete list is an excellent starting point for any secure system design, but we will focus here on the most applicable controls for securing Web service deployments.

Critical Control 3: Secure Configurations for Hardware and Software on Laptops, Workstations, and Servers

This control requires a secure configuration of all system components. It can be implemented by creating standard system images that are hardened against attacks. Such hardening may include disabling nonessential system services, limiting the visibility to network probes, configuring kernel-level security enforcement rules, and the like. A secure baseline operating system limits the potential damage that a misconfigured or compromised Web service or client can cause.

Critical Control 4: Continuous Vulnerability Assessment and Remediation

The window for attacking weak systems is significantly reduced by continuously monitoring and assessing the vulnerability profile of all deployed systems. With a comprehensive program in place, which should ideally consist of automated and human components, potential weaknesses in the Web service application runtime or the implementing code itself can be detected and fixed in near real time. This minimizes the attack window for threat actors significantly.

16. The list is available at http://www.sans.org/critical-security-controls.
17. NIST Special Publication (SP) 800-53 is a comprehensive list of information security controls and verification procedures.

Critical Control 6: Application Software Security

In the context of the SANS Top 20, this control focuses on the security of the code implementing the service itself. While other frameworks are available, the OWASP Top 10 list (see Figure 8.7) is a good starting point for assessing the security of the service and the quality of client software.

Critical Control 9: Security Skills Assessment and Appropriate Training to Fill Gaps

All personnel involved in the creation and maintenance of the Web service must be qualified to perform their job functions. While this seems like an ancient IT adage, many IT architects, developers, and administrators have a hard time staying on top of their field both from an application and a security perspective. Security training and evaluations should be part of everyone's responsibility. Exploring the usefulness of relevant security certifications for key staff members may augment this. Overall, only senior-level management sponsorship can ensure the successful implementation of this control.

Critical Control 10: Secure Configurations for Network Devices such as Firewalls, Routers, and Switches

Not only the actual business systems such as servers and client, but also the supporting network infrastructure components, need to be configured in the most secure way. This control is complementary to Critical Control 3 and should be implemented equivalently.

Critical Control 11: Limitation and Control of Network Ports, Protocols, and Services

It is crucial to have a comprehensive list of allowed ports, protocols, and system services for all active and passive network devices. Each individual component must only be allowed to perform its designated function and use the appropriate set of network resources to do so. This way compromised devices can be identified much more easily: If a server designated to provide Web service over HTTPS suddenly starts to send out border gateway protocol (BGP) messages, network monitors and intrusion detection and prevention systems can react immediately and take that system off the network to prevent unauthorized routing of data.

Critical Control 13: Boundary Defense

Firewalls and other boundary defense technologies have been available for a long time and despite their bad reputation for preventing advanced attacks, they are very useful in preventing certain classes of vulnerabilities. A solid boundary defense also enables close monitoring of data ingress and egress, and allows inspection and control of information flow from the Web service to the client and vice versa. Separating the rest of the world from the internal networks also makes monitoring of the use of ports, protocols, and service (Critical Control 11) much easier.

Critical Control 19: Secure Network Engineering

This control effectively augments and extends the concept of boundary defense (Critical Control 13) and takes a holistic approach to secure network design and monitoring. Proper network engineering includes a number of best practices, including grouping of similar systems and components (such as Web services or application servers) into groups and separating them from the rest of the network. This helps control clients' communication with the Web service and prevents clients from trying to scan the servers hosting the Web services for vulnerabilities.

Critical Control 20: Penetration Tests and Red Team Exercises

Even the best security engineering teams will make mistakes or miss possible attack vectors when protecting critical resources such as Web services. Only a comprehensive penetration test and recurring exercises can expose potential security flaws. More details on creating a test program for Web services are presented later in the chapter.

Other Resources

There are many other, often industry-specific sets of security controls that can handle Web service security. Examples include the American Institute of Certified Public Accountants (AICPA) Service Organization Controls (SOC) 2 or higher: "Controls at a Service Organizations Relevant to Security, Availability, Processing Integrity, Confidentiality, or Privacy,"[18] which specify requirements for cloud providers and can have relevance in the context of operating Web service on behalf of customers. Another set of applicable security controls includes the NIST SP 800-53 controls,[19] which include the latest revision of SOA controls.

There are other resources that address SOA-specific issues. One example is the Common Attack Pattern Enumeration and Classification (CAPEC),[20] which features a catalog of techniques used by attackers to break into systems. While this database is intended to cover

18. See http://www.aicpa.org/soc for more information on the SOC reports.
19. All NIST SPs can be found at http://csrc.nist.gov/publications/PubsSPs.html.
20. The CAPEC catalog can be found at http://capec.mitre.org.

all typical attack vectors against systems, it has a specialization for service-oriented issues. Typically, the information within the database is fairly comprehensive and not only addresses specific attack methodologies, but also defines a framework for classifying these approaches.

Figure 8.8 provides a sample CAPEC pattern that applies to SOA, in this case on WSDL scanning. It provides a fairly comprehensive set of attributes of this particular attack, and suggests possible mitigation strategies to counter this attack pattern. To use this catalog efficiently, it is recommended that one search the site on specific technologies and develop a list of countermeasures for mitigation.

Testing and Vulnerability Assessment

Testing Strategy

As identified in the SANS Top 20 list for Critical Controls, many other documentations of security best practices, testing, and continuous monitoring are central to maintaining a secure environment. While tests during the design of a software package such as a service are standard development practices,[21] the deployed service itself should be evaluated in context as well.

Such tests can include simple functional tests that verify the invocation of a service call in the deployed environment (or a mockup of that environment), but they may also include performance tests to ensure that the service behaves correctly under heavy load. A number of commercial and open source tools are available for performing such tests, including the popular soapUI framework[22] or WebInject[23] open source projects.

Vulnerability Assessment Tools

In addition to functional testing at development and deploy time, Web services should undergo at least a vulnerability assessment to determine their actual vulnerabilities (see Sidebar: Vulnerability Assessment versus Penetration Testing). Such a vulnerability assessment focuses on determining the problems with the exposed service, from a number of different angles.

21. This may include Unit testing, continuous builds, and other functional tests to verify the correct functioning of the service. For services, Unit tests may include not only API invocations of the implementing classes, but also explicit calls to the service interfaces exposed on the network. Note that configuring such tests with services that implement security functionality directly (e.g., in-code authorization) may be very complex and not necessarily feasible.

22. See http://www.soapui.org/ for information on using soapUI.

23. WebInject is available from http://www.webinject.org.

Vulnerability Assessment versus Penetration Testing

In the past, Vulnerability Assessment and Penetration Testing have sometimes been used synonymously. While their goals and sometimes the techniques are similar, there is a fundamental difference between the two:

- Vulnerability Assessments are cooperative engagements, where the security expert, the developers, and the administrators are working hand in hand to understand, document, and eliminate the vulnerabilities of the exposed services. The assessors should have full access to the source code, the interface definition (such as the WSDL for SOAP services), security documentation, and privileged access to the servers hosting the services. The end goal is a plan to improve the security posture of the deployed service.
- Penetration Tests, on the other hand, are noncooperative exercises, where the owners of the Web service are not necessarily aware of the fact that a penetration test is underway. Depending on the rules of engagement, the penetration testers (sometimes called the red team) may use a large variety of techniques to gain access or subvert a deployed service, including trying to get physical access to the hosting servers. Furthermore, the red team may operate under rules that allow them to permanently damage the deployed service in order to better understand the potential security impact of a real attack.

While penetration tests often result in more in-depth analysis of the security posture, most companies will not allow the red team to perform a full-scale attack on production systems.

To perform a comprehensive vulnerability assessment of a service installation, the analyst should be familiar with the base techniques of vulnerability assessments for servers. Many tools are available for performing such an assessment, both commercial and open source-based solutions. Specialized Linux distributions such as BackTrack Linux[24] are specifically designed for vulnerability assessments and testing, and have many of the best tools preinstalled. For HTTP-based systems, testers should minimally employ w3af, MetaSploit, openVAS, and Nessus in addition to other standard tools.

Finally, let's take a brief look at the Web applications, services, and servers challenges that still need to be addressed. The following checklist (see checklist: An Agenda for Action for Security Actions That Web Applications, Services, and Servers Need to Consider) discusses in detail the security challenges of several Web applications, services, and servers , including Web services discovery, quality of service, quality of protection, and protection from denial-of-service attacks.

24. See http://www.backtrack-linux.org/ for more information on BackTrack.

WSDL Scanning

Attack Pattern ID: 95 **Typical Severity:** High **Status:** Draft

Description

Summary

This attack targets the WSDL interface made available by a web service. The attacker may scan the WSDL interface to reveal sensitive information about invocation patterns, underlying technology implementations and associated vulnerabilities. This type of probing is carried out to perform more serious attacks (e.g. parameter tampering, malicious content injection, command injection, etc.). WSDL files provide detailed information about the services ports and bindings available to consumers. For instance, the attacker can submit special characters or malicious content to the Web service and can cause a denial of service condition or illegal access to database records. In addition, the attacker may try to guess other private methods by using the information provided in the WSDL files.

Attack Execution Flow

1. The first step is exploratory meaning the attacker scans for WSDL documents. The WDSL document written in XML is like a handbook on how to communicate with the web services provided by the target host. It provides an open view of the application (function details, purpose, functional break down, entry points, message types, etc.). This is very useful information for the attacker.
2. The second step that a attacker would undertake is to analyse the WSDL files and try to find potential weaknesses by sending messages matching the pattern described in the WSDL file. The attacker could run through all of the operations with different message request patterns until a breach is identified.
3. Once an attacker finds a potential weakness, they can craft malicious content to be sent to the system. For instance the attacker may try to submit special characters and observe how the system reacts to an invalid request. The message sent by the attacker may not be XML validated and cause unexpected behavior.

Attack Prerequisites

A client program connecting to a web service can read the WSDL to determine what functions are available on the server.

The target host exposes vulnerable functions within its WSDL interface.

Typical Likelihood of Exploit

Likelihood: High

Methods of Attack

- Analysis
- API Abuse

Examples-Instances

Description

A WSDL interface may expose a function vulnerable to SQL Injection.

Description

The Web Services Description Language (WSDL) allows a web service to advertise its capabilities by describing operations and parameters needed to access the service. As discussed in step 5 of this series, WSDL is often generated automatically, using utilities such as Java2WSDL, which takes a class or interface and builds a WSDL file in which interface methods are exposed as web services.

Because WSDL generation often is automated, enterprising hackers can use WSDL to gain insight into the both public and private services. For example, an organization converting legacy application functionality to a web services framework may inadvertently pass interfaces not intended for public consumption to a WSDL generation tool. The result will be SOAP interfaces that give access to private methods.

Another, more subtle WSDL attack occurs when an enterprising attacker uses naming conventions to guess the names of unpublished methods that may be available on the server. For example, a service that offers a stock quote and trading service may publish query methods such as requestStockQuote in its WSDL. However, similar unpublished methods may be available on the server but not listed in the WSDL, such as executeStockQuote. A persistent hacker with time and a library of words and phrases can cycle thru common naming conventions (get, set, update, modify, and so on) to discover unpublished application programming interfaces that open doors into private data and functionality.

Source : "Seven Steps to XML Mastery, Step 7: Ensure XML Security", Frank Coyle. See reference section.

Attacker Skills or Knowledge Required

Skill or Knowledge Level: Low

This attack can be as simple as reading WSDL and starting sending invalid request.

Skill or Knowledge Level: Medium

This attack can be used to perform more sophisticated attacks (SQL injection, etc.)

Probing Techniques

Description

An attacker can request the WSDL file from the target host by sending a SOAP message.

Description

There are free Vulnerability testing tool, such as WSDigger to perform WSDL scanning - Foundstone's free Web services security tool performs WSDL scanning, SQL injection and XSS attacks on Web Services.

FIGURE 8.8 Sample CAPEC for WSDL scanning.

Solutions and Mitigations

It is important to protect WSDL file or provide limited access to it.

Review the functions exposed by the WSDL interface (specially if you have used a tool to generate it). Make sure that none of them is vulnerable to injection.

Ensure the WSDL does not expose functions and APIs that were not intended to be exposed.

Pay attention to the function naming convention (within the WSDL interface). Easy to guess function name may be an entry point for attack.

Validate the received messages against the WSDL Schema. Incomplete solution.

7. CHALLENGES

While many of the Web applications, services, and server challenges have been met with existing standards, standards organizations are addressing a number of challenges, particularly in the area of Web services discovery and reliability. The Web Services Interoperability Organization (WS-I) acknowledges that many challenges remain to be addressed. Some examples of these challenges are as follows:

- Repudiation of transactions
- Secure issuance of credentials
- Exploitation of covert channels
- Compromised services
- Spread of malware, such as viruses and Trojan horses via SOAP messages
- Denial-of-service attacks
- Incorrect service implementations

8. SUMMARY

The practices recommended in this chapter are designed to help mitigate the risks associated with Web applications, services, and servers. Web applications, services, and

An Agenda for Action for Security Actions That Web Applications, Services, and Servers Need to Consider

The following items are possible actions that organizations should consider; some of the items may not apply to all organizations. In particular, it is necessary to balance these actions against budget requirements and the potential risks an organization's Web applications, services and servers may face (check all tasks completed):

_____1. **Replicate Data and Services to Improve Availability.** Since Web applications, services, and servers are susceptible to DoS attacks, it is important to replicate data and applications in a robust manner. Replication and redundancy can ensure access to critical data in the event of a fault. It will also enable the system to react in a coordinated way to deal with disruptions.

_____2. **Use Logging of Transactions to Improve Nonrepudiation and Accountability.** Nonrepudiation and accountability require logging mechanisms involved in the entire Web applications, services, and server transaction. In particular, the level of logging provided by various UDDI registries, identity providers, and individual Web services varies greatly. Where the provided information is not sufficient to maintain accountability and nonrepudiation, it may be necessary to introduce additional software or services into the SOA to support these security requirements.

_____3. **Use Threat Modeling and Secure Software Design Techniques to Protect from Attacks.** The objective of secure software design techniques is to ensure that the design and implementation of Web applications, services, and server software does not contain defects that can be exploited. Threat modeling and risk analysis techniques should be used to protect the Web services application from attacks. Used effectively, threat modeling can find security strengths and weaknesses, discover vulnerabilities, and provide feedback into the security life cycle of the application. Software security testing should include security-oriented code reviews and penetration testing. By using threat modeling and secure software design techniques, Web applications, services, and servers can be implemented to withstand a variety of attacks.

_____4. **Use Performance Analysis and Simulation Techniques for End-to-End Quality of Service and Quality of Protection.** Queuing networks and simulation techniques have long played critical roles in designing, developing, and managing complex information systems. Similar techniques can be used for quality assured and highly available Web applications, services, and servers. In addition to QoS of a single service, end-to-end QoS is critical for most composite services. For example, enterprise systems with several business partners must complete business processes in a timely manner to meet real-time market conditions. The dynamic and compositional nature of Web applications, services, and servers makes end-to-end QoS management a major challenge for service-oriented distributed systems.

_____5. **Digitally Sign UDDI Entries to Verify the Author of Registered Entries.** UDDI registries openly provide details about the purpose of a Web service as well as how to access it. Web applications, services, and servers use UDDI registries to discover and dynamically bind to Web applications, services, and servers at runtime. Should an attacker compromise a UDDI entry, it would be possible for requesters to bind to a malicious provider. Therefore, it is important to digitally sign UDDI entries so as to verify the publisher of these entries.

_____6. **Enhance Existing Security Mechanisms and Infrastructure.** Web applications, services, and servers rely on many existing Internet protocols and often coexist with other network applications on an organization's network. As such, many Web applications, services, and server security standards, tools, and techniques require that traditional security mechanisms, such as firewalls, intrusion detection systems (IDS), and secured operating systems, are in effect before implementation or deployment of Web services applications.

servers are important drivers for the software industry. The primary goal of service-oriented computing is to make a collection of software services accessible via standardized protocols whose functionality can be automatically discovered and integrated into applications. While several standards bodies (such as W3C and OASIS) are laying the foundation for Web applications, services, and servers, several research problems must be solved to make secure Web applications, services, and servers a reality. Service description, automatic service discovery, as well as QoS, are some of the important problems that need to be solved.

Web applications, services, and servers are increasingly becoming an integral part of organizational information technology (IT) infrastructures—even though there are still unmet security challenges. To this end, the development and deployment of secure Web applications, services, and servers are essential to many organizations' IT infrastructures. However, the security standards of Web applications, services, and servers do not provide all of the required properties to develop robust, secure, and reliable Web applications, services, and servers. To adequately support the needs of the Web applications,

services, and servers-based applications, effective risk management and appropriate deployment of alternate countermeasures are essential. Defense-in-depth through security engineering, secure software development, and risk management can provide much of the robustness and reliability required by these applications.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The development of a distributed hypertext system in the early 1990s at the CERN in Switzerland was one of the defining moments in making the Internet available to an audience beyond academia and specialized communities.
2. True or False? Since HTTP services implementing a REST architectural style (often called REST Services) are simply using the HTTP stack, all security aspects of HTTP apply.
3. True or False? It should be noted that since WS-Security is only tied to the SOAP messaging structures, it is completely transport independent and can therefore be used not only over the SOAP HTTP binding, but also with any other form of SOAP transport.
4. True or False? Since Web services are intended to implement a distributed architecture, it becomes very important to manage the identities of the participating actors: Different systems implementing the services or the clients need to fully understand who they are interacting with in order to make access control decisions that are consistent with the security policies for the systems.
5. True or False? Most modern operating systems support IBAC-based access control for file systems access and other security-related functions.

Multiple Choice

1. SOAP services are built around the concept of a:
   - **A.** SOAP header.
   - **B.** SOAP body.
   - **C.** SOAP envelope.
   - **D.** SOAP message.
   - **E.** All of the above.
2. The simple Base64 encoding can be decoded by anyone and must be treated as:
   - **A.** bad code.
   - **B.** clear text.
   - **C.** basic authentication.
   - **D.** server authentication.
   - **E.** All of the above.
3. What can usually make use of operating or runtime systems certificate stores in a very efficient way?
   - **A.** TLS
   - **B.** PKI
   - **C.** MAC
   - **D.** REST client libraries
   - **E.** Two
4. WS-Security[25] (often abbreviated WSS) defines a Header extension to provide a number of features for SOAP-based messages, except which two?
   - **A.** Signing the message to provide integrity protection and nonrepudiation
   - **B.** Combining WS-Security with the security mechanisms of the underlying transport security
   - **C.** Encrypting the message to provide message-level confidentiality
   - **D.** Attaching arbitrary security tokens to the messages to provide identity of the sender
   - **E.** WS-Security leveragings the XML Encryption and Signature standards.
5. The identity management community created a number of patterns that allow not only simple authentication, but also advanced patterns including the following, except which two?
   - **A.** Other patterns, such as privacy preserving authentication and authorization
   - **B.** Single Sign On (SSO) using mutually trusted identity servers
   - **C.** Federations of identity providers
   - **D.** SAML Authentication Token
   - **E.** Complex, distributed authorization

EXERCISE

Problem

When multiple requesters, providers, and intermediaries are participating in a Web service transaction, it may be necessary to coordinate them. What are the two different types of mechanisms for coordinating Web services?

Hands-On Projects

Project

Because a Web service relies on some of the same underlying HTTP and Web-based architecture as common Web applications, it is susceptible to similar threats and

25. "Web Service Security: SOAP Messaging Framework 1.1," A. Nadlin et al., OASIS Open, November 2006.

vulnerabilities. Web services security is based on what important concepts?

Case Projects

Problem

Web services rely on the Internet for communication. Because SOAP was not designed with security in mind, SOAP messages can be viewed or modified by attackers as the messages traverse the Internet. What options are available for securing Web service messages?

Optional Team Case Project

Problem

Security decisions must always be made with an understanding of the threats facing the system to be secured. While a wealth of security standards and technologies are available for securing Web services, they may not be adequate or necessary for a particular organization or an individual service. For that reason, it is important to understand the threats that face Web services so that organizations can determine which threats their Web services must be secured against. What are the top threats facing Web services today?

Chapter 9

Unix and Linux Security

Gerald Beuchelt
The MITRE Corporation[1], *Bedford, MA, U.S.A.*

When Unix was first booted on a PDP-8 computer at Bell Labs, it already had a basic notion of user isolation, separation of kernel and user memory space, and process security. It was originally conceived as a multiuser system, and as such, security could not be added on as an afterthought. In this respect, Unix was different from a whole class of computing machinery that had been targeted at single-user environments.

Linux is mostly a GNU software-based operating system with a kernel originally written by Linus Torvalds and many of the popular utilities from the GNU Software Foundation and other open source organizations added. GNU/Linux implements the same interfaces as most current Unix systems, including the Portable Operating System Interface (POSIX) standards. As such, Linux is a Unix-style operating system, despite the fact that it was not derived from the original AT&T/Bell Labs Unix code base.

Debian is a distribution originally developed by Ian Murdock of Purdue University. Debian's express goal is to use only open and free software, as defined by its guidelines. Ubuntu is a derivative Linux distribution that is based on the Debian system. It emphasizes ease of use and allows beginning users easy access to a comprehensive Linux distribution.

All versions of MacOS X are built on top of Unix operating systems, namely, the Mach microkernel and the University of California's FreeBSD code. While the graphical user interface and some other system enhancements are proprietary, MacOS has a XNU kernel and includes most of the command-line utilities commonly found in Unix operating systems.

The examples in this chapter refer to the Solaris, MacOS, and Ubuntu Linux, a distribution by Canonical Inc., built on the popular Debian distribution.

1. The opinions and guidance presented here are those of the author and do not necessarily reflect the positions of The MITRE Corporation, its customers or sponsors, or any part of the U.S. federal government.

1. UNIX AND SECURITY

As already indicated, Unix was originally created as a multiuser system. Initially, systems were not necessarily networked, but with the integration of the Berkley Software Distribution (BSD) TCP/IP V4 stack in 1984, Unix-based systems quickly became the backbone of the quickly growing Internet. As such, Unix servers started to provide critical services to network users as well.

The Aims of System Security

In general, secure computing systems must guarantee the confidentiality, integrity, and availability of resources. This is achieved through a combination of different security mechanisms and safeguards, including policy-driven access control and process separation.

Authentication

When a user is granted access to resources on a computing system, it is of vital importance to establish and verify the identity of the requesting entity. This process is commonly referred to as *authentication* (sometimes abbreviated *AuthN*).

Authorization

As a multiuser system, Unix must protect resources from unauthorized access. To protect user data from other users and nonusers, the operating system has to put up safeguards against unauthorized access. Determining the eligibility of an authenticated (or anonymous) user to access or modify a resource is usually called *authorization* (*AuthZ*).

Availability

Guarding a system (including all its subsystems, such as the network) against security breaches is vital to keep the system available for its intended use. *Availability* of a system must be properly defined: Any system is

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00009-X

The term POSIX stands (loosely) for "Portable Operating System Interface for uniX". From the IEEE 1003.1 Standard, 2004 Edition:

"This standard defines a standard operating system interface and environment, including a command interpreter (or "shell"), and common utility programs to support applications portability at the source code level. This standard is the single common revision to IEEE Std 1003.1-1996, IEEE Std 1003.2-1992, and the Base Specifications of The Open Group Single UNIX Specification, Version 2."
Partial or full POSIX compliance is often required for government contracts.

FIGURE 9.1 Various Unix and POSIX standards.

physically available, even if it is turned off; however, a shutdown system would not be too useful. In the same way, a system that has only the core operating system running but not the services that are supposed to run on the system is considered not available.

Integrity

Similar to availability, a system that is compromised cannot be considered available for regular service. Ensuring that the Unix system is running in the intended way is most crucial, especially since the system might otherwise be used by a third party for malicious uses, such as a relay or member in a botnet.

Confidentiality

Protecting resources from unauthorized access and safeguarding the content is referred to as confidentiality. As long as it is not compromised, a Unix system will maintain the confidentiality of system user data by enforcing access control policies and separating processes from each other. There are two fundamentally different types of access control: discretionary and mandatory access control. Users themselves manage the discretionary segment, while the system owner sets the mandatory. We will discuss the differences later in this chapter.

2. BASIC UNIX SECURITY OVERVIEW

Unix security has a long tradition, and though many concepts of the earliest Unix systems still apply, there have been a large number of changes that fundamentally altered the way the operating system implements these security principles.

One of the reasons that it's complicated to talk about Unix security is that there are a lot of variants of Unix and Unix-like operating systems on the market. In fact, if you only look at some of the core Portable Operating System Interface (POSIX) standards that have been set forth to guarantee minimal consistency across different Unix flavors (see Figure 9.1), almost every operating system on the market qualifies as Unix (or, more precisely, as POSIX compliant). Examples include not only the traditional Unix operating systems such as Solaris, HP-UX, or AIX but also Windows NT-based operating systems (such as Windows XP, either through the native POSIX subsystem or the Services for Windows extensions) or even z/OS.

Traditional Unix Systems

Most Unix systems do share some internal features, though: Their authentication and authorization approaches are similar, their delineation between kernel space and user space goes along the same lines, and their security-related kernel structures are roughly comparable. In the last few years, however, major advancements have been made in extending the original security model by adding role-based access control[2] (RBAC) models to some operating systems.

Kernel Space versus User Land

Unix systems typically execute instructions in one of two general contexts: the kernel or the user space. Code executed in a kernel context has (at least in traditional systems) full access to the entire hardware and software capabilities of the computing environment. Although there are some systems that extend security safeguards into the kernel, in most cases, not only can a rogue kernel execution thread cause massive data corruption, but it can effectively bring down the entire operating system.

Obviously, a normal user of an operating system should not wield so much power. To prevent this, user execution threads in Unix systems are not executed in the context of the kernel but in a less privileged context, the user space—sometimes also facetiously called user land. The Unix kernel defines a structure called *process* (see Figure 9.2) that associates metadata about the user as well as, potentially, other environmental factors with the execution thread and its data. Access to computing resources such as memory and I/O subsystems is safeguarded by

2. RBAC was developed in the 1990s as a new approach to access control for computing resources. Authorization to access resources is granted based on role membership, and often allows more fine-grained resource control since specific operations (such as "modify file" or "add printer") can be granted to role members. In 2004, the RBAC model was standardized in American National Standard 359-2004 (see also http://csrc.nist.gov/rbac/ for more information).

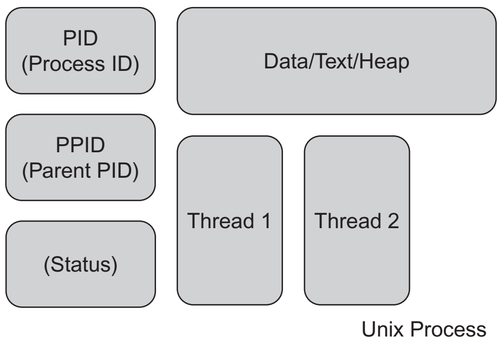

FIGURE 9.2 Kernel structure of a typical Unix process.

the kernel; if a user process wants to allocate a segment of memory or access a device, it has to make a system call, passing some of its metadata as parameters to the kernel. The kernel then performs an authorization decision and either grants the request or returns an error. It is then the process's responsibility to properly react to either the results of the access or the error.

If this model of user space process security is so effective, why not implement it for all operating system functions, including the majority of kernel operations? The answer to this question is that to a large extent the overhead of evaluating authorization metadata is very compute expensive. If most or all operations (that are, in the classical kernel space, often hardware-related device access operations) are run in user space or a comparable way, the performance of the OS would severely suffer. There is a class of operating system with a microkernel that implements this approach; the kernel contains only the most rudimentary functions (processes, scheduling, basic security), and all other operations, including device access and other operations that are typically carried out by the kernel, run in separate user processes. The advantage is a higher level of security and better safeguards against rogue device drivers. Furthermore, new device drivers or other operating system functionality can be added or removed without having to reboot the kernel. The performance penalties are so severe, however, that no major commercial operating system implements a microkernel architecture.

Many modern Unix-based systems operate in a mixed mode: While many device drivers such as hard drives, video, and I/O systems are operating in the kernel space, they also provide a framework for user space drivers. For example, the Filesystems in User Space (FUSE) allows loading additional drivers for file systems. This permits the mounting of devices that are not formatted with the default file system types that the OS supports, without having to execute with elevated privileges. It also allows the use of file systems in situations, where license conflict prevents the integration of a file system driver into the kernel (for example, the CDDL licensed ZFS file system into the GPL licensed Linux kernel).

Semantics of User Space Security

In most Unix systems, security starts with access control to resources. Since users interact with the systems through processes and files, it is important to know that every user space process structure has two important security fields: the user identifier, or UID, and the group identifier, or GID. These identifiers are typically positive integers, which are unique for each user.[3] Every process that is started[4] by or on behalf of a user inherits the UID and GID values for that user account. These values are usually immutable for the live time of the process.

Access to system resources must go through the kernel by calling the appropriate function that is accessible to user processes. For example, a process that wants to reserve some system memory for data access will use the malloc() system call and pass the requested size and an (uninitialized) pointer as parameters. The kernel then evaluates this request, determines whether enough virtual memory (physical memory plus swap space) is available, reserves a section of memory, and sets the pointer to the address where the block starts.

Users who have the UID zero have special privileges: They are considered *superusers*, able to override many of the security guards that the kernel sets up. The default Unix superuser is named *root*.

Standard File and Device Access Semantics

File access is a very fundamental task, and it is important that only authorized users get read or write access to a given file. If any user was able to access any file, there would be no privacy at all, and security could not be maintained, since the operating system would not be able to protect its own permanent records, such as configuration information or user credentials. Most Unix operating systems use an identity-based access control (IBAC) model, in which access policies are expressed in terms of the user's identity.

The most common IBAC policy describing who may access or modify files and directories is commonly referred to as an *access control list* (ACL). Note that there is more than just one type of ACL; the standard Unix ACLs are very well known, but different Unix

3. If two usernames are associated with the same UID, the operating system will treat them as the same user. Their authentication credentials (username and password) are different, but their authorization with respect to system resources is the same.

4. Processes can be "started" or created in a variety of ways, for example, by calling the fork() system call or by calling the execve() system call to load a new executable file and start it.

variants or POSIX-like operating systems might implement different ACLs and only define a mapping to the simple POSIX 1003 semantics. A good example is the Windows NTFS ACL or the NFS v4 ACLs. ACLs for files and devices represented though device files are stored within the filesystem as meta data for the file information itself. This is different from other access control models where policies may be stored in a central repository.

Read, Write, Execute

From its earliest days, Unix implemented a simple but effective way to set access rights for users. Normal files can be accessed in three fundamental ways: read, write, and execute. The first two ways are obvious; the execution requires a little more explanation. A file on disk may only be executed as either a binary program or a script if the user has the right to execute this file. If the execute permission is not set, the system call exec() or execve() to execute a file image will fail. In addition to a user's permissions, there must be a notion of ownership of files and sometimes other resources. In fact, each file on a traditional Unix file system is associated with a user and a group. The user and group are not identified by their name but by UID and GID instead.

In addition to setting permissions for the user owning the file, two other sets of permissions are set for files: for the group and for all others. Similar to being owned by a user, a file is also associated with one group. All members of this group[5] can access the file with the permissions set for the group. In the same way, the other set of permissions applies to all users of the system.

Special Permissions

In addition to the standard permissions, there are a few special permissions, discussed here.

Set-ID Bit

This permission only applies to executable files, and it can only be set for the user or the group. If this bit is set, the process for this program is not set to the UID or GID of the invoking user but instead to the UID or GID of the file. For example, a program owned by the superuser can have the Set-ID bit set and execution allowed for all users. This way a normal user can execute a specific program with elevated privileges.

5. It should be noted that users belong to one primary group, identified by the GID set in the password database. However, group membership is actually determined separately through the /etc/group file. As such, the user can be (and often is) a member of more than one group.

Sticky Bit

When the sticky bit is set on an executable file, its data (specifically the text segment) is kept in memory, even after the process exits. This is intended to speed execution of commonly used programs. A major drawback of setting the sticky bit is that when the executable file changes (for example, through a patch), the permission must be unset and the program started once more. When this process exits, the executable is unloaded from memory and the file can be changed.

Mandatory Locking

Mandatory file and record locking refers to a file's ability to have its reading or writing permissions locked while a program is accessing that file.

There might be additional implementation-specific permissions. These depend not only on the capabilities of the core operating facilities, including the kernel, but also on the type of file system. For example, most Unix operating systems can mount FAT-based file systems, which do not support any permissions or user and group ownership. Since the internal semantics require some values for ownership and permissions, these are typically set for the entire file system.

Permissions on Directories

The semantics of permissions on directories (see Figure 9.3) are different from those on files.

Read and Write

Mapping these permissions to directories is fairly straightforward: The read permission allows listing files in the directory, and the write permission allows us to create files. For some applications it can be useful to allow writing but not reading.

Execute

With this permission, a process can set its working directory to this directory. Note that with the basic permissions, there is no limitation on traversing directories, so a process might change its working directory to a child of a directory, even if it cannot do so for the directory itself.

SetID

Semantics may differ here. For example, on Solaris this changes the behavior for default ownership of newly created files from the System V to the BSD semantics.

Other File Systems

As mentioned, the set of available permissions and authorization policies depends on the underlying operating

```
Making a directory readable for everyone:

# chmod o+r /tmp/mydir
# ls -ld /tmp/mydir

drwxr-xr-x   2 root     root         117 Aug  9 12:12 /tmp/mydir

Setting the SetID bit on an executable, thus enabling it to be run with super-user privileges:

# chmod u+s specialprivs
# ls -ld specialprivs

-rwsr-xr-x   2 root     root         117 Aug  9 12:12 specialprivs
```

FIGURE 9.3 Examples of chmod for files and directories.

system capabilities, including the file system. For example, the UFS file system in Solaris since version 2.5 allows additional ACLs on a per-user basis. Furthermore, NFS version 4 or higher defines additional ACLs for file access; it is obvious that the NFS server must have an underlying files system capable of recording this additional metadata.

Discretionary Versus Mandatory Access Control

The access control semantics described so far establish a "discretionary" access control (DAC) model: Any user may determine what type of access he or she wants to give to other specific users, groups, or anybody else. For many applications this is sufficient: For example, for systems that deliver a single network service and do not allow interactive login, the service's ability to determine what data will be shared with network users may be sufficient.

In systems that need to enforce access to data based on centralized, system operator- administered policies, DAC may not be sufficient. For example, for systems that need to operate in Multi-Level Security (MLS) environments, confidentiality of data can only be achieved through a mandatory access control (MAC) model. A number of MAC implementations for Unix-based systems are currently available, including Solaris Trusted Extensions for Solaris 10, SELinux for Linux-based operating systems, and TrustedBSD for BSD-based distributions.

Mandatory access control can be designed and implemented in many different ways. A common approach is to label operating system objects both in user and kernel space with a classification level and enforce appropriate MAC policies, such as the Bell-LaPadua (BLP) model for data confidentiality or the Biba model for data integrity.

Many Unix operating systems today provide a rudimentary set of MAC options by default: The SELinux based Linux Security Module (LSM) interface is now part of the core kernel, and some operating system vendors such as Red Hat ship their OSes with a minimal set of MAC policies enabled. To operate in a true Multi-Level Security environment, further configuration and often additional software modules are necessary to enable a BLP or Biba compliant set of MAC policies.

While MAC-based systems have traditionally been employed in government environments, modern enterprise architectures have a growing need for enforced access control around confidentiality or integrity. For example, data leakage protection (DLP) systems or auditing systems will benefit from certain types of centralized MAC policies.

3. ACHIEVING UNIX SECURITY

Achieving a high level of system security for the Unix system is a complex process that involves technical, operational, and managerial aspects of system operation. Next is a very cursory overview of some of the most important aspects of securing a Unix system.

System Patching

Prior to anything else, it is vitally important to emphasize the need to keep Unix systems up to date. No operating system or other program can be considered safe without being patched up; this point cannot be stressed enough. Having a system with the latest security patches is the first and most often the best line of defense against intruders and other cyber security threats.

All major Unix systems have a patching mechanism; this is a way to get the system up to date. Depending on the vendor and the mechanism used, it is possible to "back out" the patches. For example, on Solaris it is

usually possible to remove a patch through the patchrm (1 m) command. On Debian-based systems this is not quite as easy, since in a patch the software package to be updated is replaced by a new version. Undoing this is only possible by installing the earlier package.

Locking Down the System

In general, all system services and facilities that are not needed for regular operation should be disabled or even uninstalled. Since any software package increases the attack surface of the system, removing unnecessary software ensures a better security posture.

Minimizing User Privileges

User accounts that have far-reaching access rights within a system have the ability to affect or damage a large number of resources, potentially including system management or system service resources. As such, user access rights should be minimized by default, in line with the security principle of "least privilege." For example, unless interactive access to the system is absolutely required, users should not be permitted to login.

Detecting Intrusions with Audits and Logs

By default, most Unix systems log kernel messages and important system events from core services. The most common logging tool is the syslog facility, which is controlled from the /etc/syslog.conf file.

4. PROTECTING USER ACCOUNTS AND STRENGTHENING AUTHENTICATION

In general, a clear distinction must be made between users obtaining a command shell for a Unix system ("interactive users") and consumers of Unix network services ("noninteractive users"). The interactive users should in most instances be limited to administrators that need to configure and monitor the system, especially since interactive access is almost always a necessary first step to obtain administrative access.

Establishing Secure Account Use

For any interactive session, Unix systems require the user to log into the system. To do so, the user must present a valid credential that identifies him (he or she must authenticate to the system). The type of credentials a Unix system uses depends on the capabilities of the OS software itself and on the configuration set forth by the systems administrator. The most traditional user credential is a username and a text password, but there are many other ways to authenticate to the operating system, including Kerberos, SSH, or security certificates.

The Unix Login Process

Depending on the desired authentication mechanism (see Figure 9.4), the user will have to use different access protocols or processes. For example, console or directly attached terminal sessions usually support only password credentials or smart card logins, whereas a secure shell connection supports only RSA- or DSA-based cryptographic tokens over the SSH protocol.

The login process is a system daemon that is responsible for coordinating authentication and process setup for interactive users. To do this, the login process does the following:

1. Draw or display the login screen.
2. Collect the credential.
3. Present the user credential to any of the configured user databases (typically, these can be files, NIS, Kerberos servers, or LDAP directories) for authentication.
4. Create a process with the user's default command-line shell, with the home directory as working directory.
5. Execute systemwide, user, and shell-specific start-up scripts.

The commonly available X11 windowing system does not use the text-oriented login process but instead provides its own facility to perform roughly the same kind of login sequence.

Overview of Unix authentication methods

- Simple: a username and a password are used to login to the operating system. The login process must receive both in cleartext. For the password, the Unix crypt hash is calculated and compared to the value in the password or shadow file.
- Kerberos: The user is supposed to have a ticket-granting ticket from the Kerberos Key Distribution Server (KDC). Using the ticket-granting ticket, he obtains a service ticket for an interactive login to the Unix host. This service ticket (encrypted, time limited) is then presented to the login process, and the Unix host validates it with the KDC.
- PKI based Smartcard: the private key on the smart card is used to authenticate with the system.

FIGURE 9.4 Various authentication mechanisms for Unix systems.

Access to interactive sessions using the SSH protocol follows a similar general pattern, but the authentication is significantly different from the traditional login process.

Controlling Account Access

Simple files were the first method available to store user account data. Over the course of years many other user databases have been implemented. We examine these here.

The Local Files

Originally, Unix only supported a simple password file for storing account information. The username and the information required for the login process (UID, GID, shell, home directory, and GECOS information) are stored in this file, which is typically at /etc/passwd. This approach is highly insecure, since this file needs to be readable by all for a number of different services, thus exposing the password hashes to potential hackers. In fact, a simple dictionary or even brute-force attack can reveal simple or even more complex passwords.

To protect against an attack like this, most Unix variants use a separate file for storing the password hashes (/etc/shadow) that is only readable and writable by the system.

Network Information System

The Network Information System (NIS) was introduced to simplify the administration of small groups of computers. Originally, Sun Microsystems called this service Yellow Pages, but the courts decided that this name constituted a trademark infringement on the British Telecom Yellow Pages. However, most commands that are used to administer the NIS still start with the yp prefix (such as ypbind and ypcat).

Systems within the NIS are said to belong to a NIS domain. Although there is absolutely no correlation between the NIS domain and the DNS domain of the system, it is quite common to use DNS-style domain names for naming NIS domains. For example, a system with DNS name system1.sales.example.com might be a member of the NIS domain nis.sales.Example.COM. Note that NIS domains—other than DNS domains—are case sensitive.

The NIS uses a simple master/slave server system: The master NIS server holds all authoritative data and uses an ONC-RPC-based protocol to communicate with the slave servers and clients. Slave servers cannot be easily upgraded to a master server, so careful planning of the infrastructure is highly recommended.

Client systems are bound to one NIS server (master or slave) during runtime. The addresses for the NIS master and the slaves must be provided when joining a system to the NIS domain. Clients (and servers) can always be members of only one NIS domain. To use the NIS user database (and other NIS resources, such as auto-mount maps, netgroups, and host tables) after the system is bound, use the name service configuration file (/etc/nsswitch.conf), as shown in Figure 9.5.

Using PAMs to Modify AuthN

These user databases can easily be configured for use on a given system through the /etc/nsswitch.conf file. However, in more complex situations, the administrator might want to fine-tune the types of acceptable authentication methods, such as Kerberos, or even configure multifactor authentication. Traditionally, the PAM is configured through the /etc/pam.conf file, but more modern implementations use a directory structure, similar to the System V init scripts. For these systems, the administrator needs to modify the configuration files in the /etc/pam.d/ directory.

```
# /etc/nsswitch.conf

#
# Example configuration of GNU Name Service Switch functionality.
#
passwd:         files nis

group:          files nis
shadow:         files nis

hosts:          files nis dns
networks:       files

protocols:      db files
services:       db files
ethers:         db files
rpc:            db files
netgroup:       nis
```

FIGURE 9.5 Sample nsswitch.conf for a Debian system.

```
# /etc/pam.d/common-password - password-related modules common to all services
#

# This file is included from other service-specific PAM config files,
# and should contain a list of modules that define the services to be
# used to change user passwords.  The default is pam_unix.

# Explanation of pam_unix options:
#
# The "nullok" option allows users to change an empty password, else
# empty passwords are treated as locked accounts.
#

# The "md5" option enables MD5 passwords.  Without this option, the
# default is Unix crypt.
#

# The "obscure" option replaces the old `OBSCURE_CHECKS_ENAB' option in
# login.defs.
#

# You can also use the "min" option to enforce the length of the new
# password.
#
# See the pam_unix manpage for other options.

password   requisite   pam_unix.so nullok obscure md5

# Alternate strength checking for password. Note that this
# requires the libpam-cracklib package to be installed.
# You will need to comment out the password line above and
# uncomment the next two in order to use this.
# (Replaces the `OBSCURE_CHECKS_ENAB', `CRACKLIB_DICTPATH')
#

password required   pam_cracklib.so retry=3 minlen=6 difok=3

password required   pam_unix.so use_authtok nullok md5
```

FIGURE 9.6 Setting the password strength on a Debian-based system through the PAM system.

Using the systemauth PAM, administrators can also enforce users to create and maintain complex passwords, including the setting of specific lengths, minimal number or numeric or nonletter characters, and so on. Figure 9.6 illustrates a typical systemauth PAM configuration.

Noninteractive Access

The security configuration of noninteractive services can vary quite significantly. Especially popular network services, such as LDAP, HTTP, or Windows File Shares (CIFS), can use a wide variety of authentication and authorization mechanisms that do not even need to be provided by the operating system. For example, an Apache Web server or a MySQL database server might use its own user database, without relying on any operating system services such as passwd files or LDAP directory authentication.

Monitoring how noninteractive authentication and authorization are performed is critically important since most users of Unix systems will only utilize them in noninteractive ways. To ensure the most comprehensive control over the system, it is highly recommended that the suggestions presented in this chapter be followed to minimize the attack surface and verify that the system makes only a clearly defined set of services available on the network.

Other Network Authentication Mechanisms

In 1983, BSD introduced the rlogin service. Unix administrators have been using RSH, RCP, and other tools from this package for a long time; they are very easy to use and configure and provide simple access across a small network of computers. The login was facilitated through a very simple trust model: Any user could create a .rhosts file in her home directory and specify foreign hosts and users from which to accept logins without proper credential checking. Over the rlogin protocol (TCP 513), the username of the rlogin client would be transmitted to the

host system, and in lieu of an authentication, the rshd daemon would simply verify the preconfigured values. To prevent access from untrusted hosts, the administrator could use the /etc/hosts.equiv file to allow or deny individual hosts or groups of hosts (the latter through the use of NIS netgroups).

Risks of Trusted Hosts and Networks

Since no authentication ever takes place, this trust mechanism should not be used. Not only does this system rely entirely on the correct functioning of the hostname resolution system, but in addition, there is no way to determine whether a host was actually replaced.[6] Also, although rlogin-based trust systems might work for very small deployments, they become extremely hard to set up and operate with large numbers of machines.

Replacing Telnet, Rlogin, and FTP Servers and Clients with SSH

The most sensible alternative to the traditional interactive session protocols such as Telnet is the Secure Shell (SSH) system. It is very popular on Unix systems, and pretty much all versions ship with a version of SSH. Where SSH is not available, the open source package OpenSSH can easily be used instead.[7]

SSH combines the ease-of-use features of the rlogin tools with a strong cryptographic authentication system. On one hand, it is fairly easy for users to enable access from other systems; on the other hand, the secure shell protocol uses strong cryptography to:

- Authenticate the connection, that is, establish the authenticity of the user
- Protect the privacy of the connection through encryption
- Guarantee the integrity of the channel through signatures

This is done using either the RSA or DSA security algorithm, which are both available for the SSH v2[8] protocol. The cipher (see Figure 9.7) used for encryption can be explicitly selected.

```
$ ssh host -luser1 -c aes192-cbc
```

FIGURE 9.7 Create an interactive session on Solaris to host for user1 using the AES cipher with 192 bits.

The user must first create a public/private key pair through the ssh-keygen(1) tool. The output of the key generator is placed in the .ssh subdirectory of the user's home directory. This output consists of a private key file called id_dsa or id_rsa. This file must be owned by the user and can only be readable by the user. In addition, a file containing the public key is created, named in the same way, with the extension .pub appended. The public key file is then placed into the .ssh subdirectory of the user's home directory on the target system.

Once the public and private keys are in place and the SSH daemon is enabled on the host system, all clients that implement the SSH protocol can create connections. There are four common applications using SSH:

- Interactive session is the replacement for Telnet and rlogin. Using the ssh(1) command line, the sshd daemon creates a new shell and transfers control to the user.
- In a remotely executed script/command, ssh(1) allows a single command with arguments to pass. This way, a single remote command (such as a backup script) can be executed on the remote system as long as this command is in the default path for the user.
- An SSH-enabled file transfer program can be used to replace the standard FTP or FTP over SSL protocol.
- Finally, the SSH protocol is able to tunnel arbitrary protocols. This means that any client can use the privacy and integrity protection offered by SSH. In particular, the X-Window system protocol can tunnel through an existing SSH connection by using the -X command-line switch.

5. LIMITING SUPERUSER PRIVILEGES

The superuser[9] has almost unlimited power on a Unix system, which can be a significant problem. On systems that implement mandatory access controls, the superuser account can be configured to not affect user data, but the problem of overly powerful root accounts for standard, DAC-only systems remains. For an organizational and managerial perspective, access to privileged functions on a Unix operating system should be tightly controlled. For example, operators that have access to privileged functions on a Unix system should not only undergo special

6. This could actually be addressed through host authentication, but it is not a feature of the rlogin protocol.

9. In all Unix systems "root" is the default name for the superuser. Access to the superuser account may be disabled by default, and administrative access is only granted temporarily to users through the sudo(1) facility.

training, but also have be investigated for their personal background. Finally, it may be advisable to enforce a policy where operators of critical systems can only access privileged functions with at least two operators present (through multifactor authentication technologies).

There are a number of technical ways to limit access for the root user:

Configuring Secure Terminals

Most Unix systems allow us to restrict root logins to special terminals, typically the system console. This approach is quite effective, especially if the console or the allowed terminals are under strict physical access control. The obvious downside of this approach is that remote access to the system can be very limited: using this approach, access through any TCP/IP-based connection cannot be configured, thus requiring a direct connection, such as a directly attached terminal or a modem.

Configuration is quite different for the various Unix systems. Figure 9.8 shows the comparison between Solaris and Debian.

Gaining Root Privileges with su

The su(1) utility allows changing the identity of an interactive session. This is an effective mediation of the issues that come with restricting root access to secure terminals: Although only normal users can get access to the machine through the network (ideally by limiting the access protocols to those that protect the privacy of the communication, such as SSH), they can change their interactive session to a superuser session.

Using Groups Instead of Root

If users should be limited to executing certain commands with superuser privileges, it is possible and common to create special groups of users. For these groups, we can set the execution bit on programs (while disabling execution for all others) and the SetID bit for the owner, in this case the superuser. Therefore, only users of such a special group can execute the given utility with superuser privileges.

Using the sudo(1) Mechanism

By far more flexible and easier to manage than the approach for enabling privileged execution based on groups is the sudo(1) mechanism. Originally an open source program, sudo(1) is available for most Unix distributions. The detailed configuration is quite complex, and the manual page is quite informative.

6. SECURING LOCAL AND NETWORK FILE SYSTEMS

For production systems, there is a very effective way of preventing the modification of system-critical resources by unauthorized users or malicious software. Critical portions of the file systems (such as the locations of binary files, system libraries, and some configuration files) do not necessarily change very often.

Directory Structure and Partitioning for Security

In fact, any systemwide binary code should probably only be modified by the systems administrators. In these cases, it is very effective to properly partition the file system.

Employing Read-Only Partitions

The reason to properly partition the file system (see Figure 9.9) is so that only frequently changing files (such as user data, log files, and the like) are hosted on readable file systems. All other storage can then be mounted on read-only partitions.

Finding Special Files

To prevent inadvertent or malicious access to critical data, it is vitally important to verify the correct ownership and permission set for all critical files in the file system.

Ownership and Access Permissions

The Unix find(1) command is an effective way to locate files with certain characteristics. In the following, a number of sample command-line options for this utility are given to locate files.

Locate SetID Files

Since executables with the SetID bit set are often used to allow the execution of a program with superuser privileges, it is vitally important to monitor these files on a regular basis.

Another critical permission set is that of world-writable files; there should be no system-critical files in this list, and users should be aware of any files in their home directories that are world-writable (see Figure 9.10). Finally, files and directories that are not owned by current users can be found by the code shown in Figure 9.11. For groups, just use -nogroup instead.

FIGURE 9.8 Restricting root access.

On Solaris simply edit the file /etc/default/login:

```
# Copyright 2004 Sun Microsystems, Inc.  All rights reserved.
# Use is subject to license terms.

# If CONSOLE is set, root can only login on that device.
# Comment this line out to allow remote login by root.
#

CONSOLE=/dev/console

# PASSREQ determines if login requires a password.
#

PASSREQ=YES

# SUPATH sets the initial shell PATH variable for root
#

SUPATH=/usr/sbin:/usr/bin

# SYSLOG determines whether the syslog(3) LOG_AUTH facility should be used
# to log all root logins at level LOG_NOTICE and multiple failed login
# attempts at LOG_CRIT.
#

SYSLOG=YES

# The SYSLOG_FAILED_LOGINS variable is used to determine how many failed
# login attempts will be allowed by the system before a failed login
# message is logged, using the syslog(3) LOG_NOTICE facility.  For
example,
# if the variable is set to 0, login will log -all- failed login attempts.
#

SYSLOG_FAILED_LOGINS=5
```

On Debian:

```
# The PAM configuration file for the Shadow `login' service
#

# Disallows root logins except on tty's listed in /etc/securetty
# (Replaces the `CONSOLE' setting from login.defs)

auth       requisite  pam_securetty.so
# Disallows other than root logins when /etc/nologin exists
# (Replaces the `NOLOGINS_FILE' option from login.defs)

auth       requisite  pam_nologin.so

# Standard Un*x authentication.

@include common-auth

# This allows certain extra groups to be granted to a user
# based on things like time of day, tty, service, and user.
# Please edit /etc/security/group.conf to fit your needs
# (Replaces the `CONSOLE_GROUPS' option in login.defs)
```

```
auth       optional   pam_group.so

# Uncomment and edit /etc/security/time.conf if you need to set
# time restrainst on logins.
# (Replaces the `PORTTIME_CHECKS_ENAB' option from login.defs
# as well as /etc/porttime)

account    requisite  pam_time.so

# Uncomment and edit /etc/security/access.conf if you need to
# set access limits.
# (Replaces /etc/login.access file)

account  required       pam_access.so

# Sets up user limits according to /etc/security/limits.conf
# (Replaces the use of /etc/limits in old login)

session    required   pam_limits.so

# Prints the last login info upon succesful login
# (Replaces the `LASTLOG_ENAB' option from login.defs)

session    optional   pam_lastlog.so

# Standard Un*x account and session

@include common-account
@include common-session
@include common-password
```

FIGURE 9.8 (Continued).

The following scheme is a good start for partitioning with read-only partitions:

- Binaries and Libraries: /bin, /lib, /sbin, /usr - read-only
- Logs and frequently changing system data: /var, /usr/var - writable
- User home directories: /home, /export/home - writable
- Additional software packages: /opt, /usr/local - read-only
- System configuration: /etc, /usr/local/etc - writable
- Everything else: Root (/) - read-only

Obviously, this can only be a start and should be evaluated for each system and application. Updating operating system files, including those on the root file system, should be performed in single-user mode with all partitions mounted writable.

FIGURE 9.9 Secure partitioning.

Locate Suspicious Files and Directories

Malicious software is sometimes stored in nonstarted directories such as subdirectories named "..." that will not immediately be noticed. Administrators should pay special attention to such files and verify if the content is part of a legitimate software package.

7. NETWORK CONFIGURATION

Since many Unix systems today are used as network servers, most users will never log in these systems interactively. Consequently, the most significant threat sources for Unix- based systems are initially defective or badly configured network services. However, such initial attacks are often only used to get initial interactive access to the system; once an attacker can access a command-line shell, other layers of security must be in place to prevent an elevation of privileges (superuser access).

Basic Network Setup

Unix user space processes can access networks by calling a variety of functions from the system libraries, namely, the socket() system call and related functions. While other network protocols such as DECNet or IPX may still be supported, the TCP/IP family of protocols plays by far the most important role in today's networks. As such, we will focus on these protocols alone. A number of files are relevant for configuring access to networks, with some of the most important listed here:

```
$ find /  \( -perm -04000 -o -perm -02000\) -type f -xdev -print
```

FIGURE 9.10 Finding files with SUID and SGID set.

```
$ find / -nouser
```

FIGURE 9.11 Finding files without users.

1. /etc/hostname (and sometimes also /etc/nodename) set the name under which the system identifies itself. This name is also often used to determine its own IP address, based on hostname resolution.
2. /etc/protocols defines the available list of protocols such as IP, TCP, ICMP, and UDP.
3. /etc/hosts and /etc/networks files define what IP hosts and networks are locally known to the system. They typically include the localhost definition (which is always 127.0.0.1 for IPv4 networks) and the loopback network (defined to be 127.0.0.0/24), respectively.
4. /etc/nsswitch.conf is available on many Unix systems and allows fine-grained setting of name resolution for a number of network and other resources, including the UIDs and GIDs. Typical settings include purely local resolution (i.e., through the files in the /etc directory), resolution through NIS, host resolution through DNS, user and group resolution through LDAP, and so on.
5. /etc/resolv.conf is the main configuration file for the DNS resolver libraries used in most Unix systems. It points to the IP addresses of the default DNS nameservers and may include the local domainname and any other search domains.
6. /etc/services (and/or /etc/protocols) contains a list of well-known services and the port numbers and protocol types they are bound to. Some system commands (such as netstat) use this database to resolve ports and protocols into user-friendly names.

Depending on the Unix flavor and the version, many other network configuration files apply to the base operating system. In addition, many other services that are commonly used on Unix systems such as HTTP servers, application servers, and databases have their own configuration files that will need to be configured and monitored in deployed systems.

Detecting and Disabling Standard UNIX Services

To protect systems against outside attackers and remove the overall attack surface, it is highly recommended to disable any service not needed for providing the intended functionality. The following simple process will likely turn off most system services that are not needed:

1. Examine the start-up scripts for your system. Start-up procedures have been changing for Unix systems quite significantly over time. Early systems used the /etc/inittab to determine runlevels and start-up scripts. Unix System V introduced the /etc/init.d scripts and the symbolic links from the /etc/rc*.d/ directories. Most current Unix systems either still use this technology or implement an interface to start and stop services (like Solaris). Debian-based distributions have a System V backward compatibility facility. Administrators should determine their start-up system and disable any services and feature not required for the function of that system. Ideally, facilities and services not needed should be uninstalled to minimize the potential attack surface for both external attacks, as well as privilege escalation attacks by running potentially harmful binaries.
2. Additionally, administrator can examine the processes that are currently running on a given system (e.g., through running the ps(1) command). Processes that cannot be traced to a particular software package or functionality should be killed and their file images ideally uninstalled or deleted.
3. The netstat(1) command can be used to display currently open network sockets, specifically for TCP and UDP connections. By default, netstat(1) will use the /etc/services and /etc/protocols databases to map numeric values to well-known services. Administrators should verify that there are only those ports open that are expected to be used by the software installed on the system.

Host-Based Firewall

One of the best ways to limit the attack surface for external attackers is to close down all network sockets that are not being actively used by network clients. This is true for systems attached directly to the Internet as well as for systems on private networks. The IP stacks of most Unix systems can be configured to only accept specific protocols (such as TCP) and connections on specific ports (such as port 80). Figure 9.12 shows how to limit ssh(1) access to systems on a specific IP subnet. Depending on the network stack, this can be achieved with a setting in the System Preferences for MacOS, or the iptables(1) command for Linux systems.

Restricting Remote Administrative Access

If possible, interactive access to Unix-based systems should be limited to dedicated administrative terminals.

```
iptables -A INPUT -i eth0 -p tcp -s 192.168.1.0/24 --dport 22 -m state --state
NEW,ESTABLISHED -j ACCEPT
iptables -A OUTPUT -o eth0 -p tcp --sport 22 -m state --state ESTABLISHED -j ACCEPT
```

FIGURE 9.12 Configuration for iptables(1) for allowing ssh(1) connections from IP address range 192.168.1.1–192.168.1.254. This can be used to limit interactive access, as described in Chapter 8.

This may be achieved by limiting root access to directly attached consoles and terminals, or by creating dedicated private networks for the express purpose of allowing remote access through ssh(1), SNMP, or Web administration utilities.

Consoles and Terminals on Restricted Networks

As described earlier, root access to terminals can be limited to specific devices such as terminals or consoles. If the terminals or consoles are provided through TCP/IP-capable terminal concentrators or KVM-switches, interactive network access can be achieved by connecting these console devices through restricted networks to dedicated administrative workstations.

Dedicated Administrative Networks

Similarly, interactive access can be restricted to a small number of workstation and access points through the following technologies:

- Dedicated physical interface or VLAN segmentation—If any interactive or administrative access is limited to separate networks, preferably disconnected from operational networks, the potential attack surface is significantly reduced.
- Logical interface—If no physical or VLAN infrastructure is available, Unix networking stacks typically allow the assignment of additional IP addresses to a single physical networking interface. While more susceptible to lower-level attacks, this approach may still be sufficient for effective separation of networks.
- Routing and firewall table design—As a fairly high-level approach, administrators may limit access to specific services from preconfigured IP addresses or networks through careful design of the host-based firewall and the routing tables of the IP stack.
- Yale University has a somewhat old, but still useful, Unix networking checklist at http://security.yale.edu/network/unix.html that describes a number of general security settings for Unix systems in general, and Solaris specifically. A similar older checklist is also available from the Carnegie Mellon University's Software Engineering Institute CERT at https://www.cert.org/tech_tips/unix_configuration_guidelines.html.
- Special topics in system administration that also address security topics such as auditing, configuration management, and recovery can be found on the Usenix Web site at https://www.usenix.org/lisa/books.
- Apple provides a detailed document on locking down MacOS X 10.6 Server: http://images.apple.com/support/security/guides/docs/SnowLeopard_Server_Security_Config_v10.6.pdf.
- The U.S. federal government operates a Computer Emergency Readiness Team (US-CERT) at https://www.us-cert.gov, targeted at technical and nontechnical users for both the government and the private sector. In addition to general information, the US-CERT provides information from the National Vulnerability Database (NVD), security bulletins, and current threat information.

Finally, let's briefly look at how to improve the security of Linux and Unix systems. The following part of the chapter, describes how to modify Linus and Unix systems and fix their potential security weaknesses.

8. IMPROVING THE SECURITY OF LINUX AND UNIX SYSTEMS

A security checklist should be structured to follow the life cycle of Linus and Unix systems, from planning and installation to recovery and maintenance. The checklist is best applied to a system before it is connected to the network for the first time. In addition, the checklist can be reapplied on a regular basis, to audit conformance (see checklist: An Agenda for Action for Linux and Unix Security Activities).

9. ADDITIONAL RESOURCES

There is a large number of very useful tools to assist administrators in managing Unix systems. This also includes verifying their security.

Useful Tools

The following discussion of useful tools should not be regarded as exhaustive. Rather, it should be seen as a simple starting point.

An Agenda for Action for Linux and Unix Security Activities

No two organizations are the same, so in applying the checklist, consideration should be given to the appropriateness of each action to your particular situation. Rather than enforcing a single configuration, the following checklist will identify the specific choices and possible security controls that should be considered at each stage, which includes the following key activities (check all tasks completed):

Determine Appropriate Security

_____**1.** Computer role.
_____**2.** Assess security needs of each kind of data handled.
_____**3.** Trust relationships.
_____**4.** Uptime requirements and impact if these are not met.
_____**5.** Determine minimal software packages required for role.
_____**6.** Determine minimal net access required for role.

Installation

_____**7.** Install from trusted media.
_____**8.** Install while not connected to the Internet.
_____**9.** Use separate partitions.
_____**10.** Install minimal software.

Apply All Patches and Updates

_____**11.** Initially apply patches while offline.
_____**12.** Verify integrity of all patches and updates.
_____**13.** Subscribe to mailing lists to keep up to date.

Minimize

_____**14.** Minimize network services.
_____**15.** Disable all unnecessary start-up scripts.
_____**16.** Minimize SetUID/SetGID programs.
_____**17.** Other minimization.

Secure Base OS

_____**18.** Physical, console, and boot security.
_____**19.** User logons.
_____**20.** Authentication.
_____**21.** Access control.
_____**22.** Other.

Secure Major Services

_____**23.** Confinement.
_____**24.** tcp_wrappers.
_____**25.** Other general advice for services.
_____**26.** SSH.
_____**27.** Printing.
_____**28.** RPC/portmapper.
_____**29.** File services NFS/AFS/Samba.
_____**30.** The X Window System.
_____**31.** DNS service.
_____**32.** WWW service.
_____**33.** Squid proxy.
_____**34.** CVS.
_____**35.** Web browsers.
_____**36.** FTP service.

Add Monitoring Capability

_____**37.** syslog configuration.
_____**38.** Monitoring of logs.
_____**39.** Enable trusted audit subsystem if available.
_____**40.** Monitor running processes.
_____**41.** Host-based intrusion detection.
_____**42.** Network intrusion detection.

Connect to the Net

_____**43.** First put in place a host firewall.
_____**44.** Position the computer behind a border firewall.
_____**45.** Network stack hardening/sysctls.
_____**46.** Connect to network for the first time.

Test Backup/Rebuild Strategy

_____**47.** Backup/rebuild strategy.
_____**48.** TEST backup and restore.
_____**49.** Allow separate restore of software and data.
_____**50.** Repatch after restoring.
_____**51.** Process for intrusion response.

Maintain

_____**52.** Mailing lists.
_____**53.** Software inventory.
_____**54.** Rapid patching.
_____**55.** Secure administrative access.
_____**56.** Log book for all sysadmin work.
_____**57.** Configuration change control with.
_____**58.** Regular audit.

Webmin

Webmin is a useful general-purpose graphical system management interface that is available for a large number of Unix systems. It is implemented as a Web application running on port 10,000 by default. Webmin allows management of basic Unix functionality such as user and group management, network and printer configuration, file system management, and many more. It also comes with a module for managing commonly used services such as the OpenLDAP directory server, the BIND DNS server, a number of different mail transfer agents, and databases.

Webmin is particularly useful for casually maintained systems that do not require tight configuration management and may expose a Web application interface. It is not recommended to use Webmin on mission-critical systems or in environments where systems are exposed to unknown external users (such as on the Internet or on large private networks). Even for systems where Webmin is an acceptable risk, it is recommended to ensure that the web interface is protected by transport-level security

(HTTP with SSL), and preferably restricted to dedicated administration networks or stations.

nmap

For testing the open ports on a given host or subnet, nmap is an excellent tool. It allows scanning a given IP address or IP address range and testing what TCP and UDP ports are accessible. It is very flexible and can easily be extended, but it comes with a number of modules that allow determining the operating systems of an IP responder based on the fingerprint of the TCP/IP stack responses.

LCFG

Local ConFiGiguration System (LCFG) is an effective configuration management system for complex Unix deployments. It compiles machine-specific and default configurations for all aspects of a given Unix system into an XML file and distributes these files to the client machines. More information on LCFG can be found at http://www.lcfg.org/.

Further Information

Since this chapter can only provide an introduction to fully securing Unix-based systems, the following list of resources is recommended for a more in-depth treatment of this topic. Users are also advised to consult vendor-specific information about secure configuration of their products.

By far the most comprehensive guidance on security configuration for Unix systems is available through the U.S. Defense Information Systems Agency (DISA). DISA and the National Institutes for Standards and Technology (NIST) create, publish, and update Security Technical Implementation Guides (STIGs) for a number of operating systems at http://iase.disa.mil/stigs/os/. Beyond the general STIG for Unix security, there are vendor- specific STIGs for Red Hat Linux, Solaris, HP-UX, and AIX.

10. SUMMARY

This chapter covered communications interfaces between HP-UX, Solaris, Linux, and AIX servers and the communications infrastructure (firewalls, routers, etc.). The use of Oracle in configuring and managing HP-UX, Solaris, Linux and AIX servers to support large databases and applications was also discussed.

Other Unix systems discussed included Solaris, Linux, and AIX, and material was presented on how to perform alternate Information Assurance Officer duties for HP-UX, Solaris, Linux and AIX midtier systems. This chapter also showed entry-level security professionals how to provide support for Unix security error diagnosis, testing strategies, and resolution of problems, which, is normally found in the SMC Ogden server HP-UX, AIX, Solaris, and Linux environments. In addition, the chapter showed security professionals how to provide implementation of DISA security requirements (STIG) and Unix SRR.

This chapter also helped security professionals gain experience in the installation and management of applications in Unix/Sun/Linux/AIX environments. In addition, it showed security professionals how to apply Defense Information Systems Agency (DISA) Security Technical Information Guidelines (STIG) with regard to installing and configuring/setting up Unix/Linux environments under mandatory security requirements.

The chapter showed security professionals how to work with full life-cycle information technology projects; as well as, provides proficiency in the environments of J2EE, EJB, Sun Solaris, IBM WebSphere, Oracle, DB/2, Hibernate, JMS/MQ Series, Web Service, SOAP, and XML. It also helped Unix/Solaris administrators on a large scale, with reference to multiuser enterprise systems.

With regard to certification exams, this chapter is designed to help students gain general experience (which includes operations experience) on large-scale computer systems or multiserver local area networks; broad knowledge and experience with system technologies (including networking concepts, hardware, and software); and the capability to determine system and network and application performance capabilities. It can also help students gain specialized experience in administrating Unix-based systems and Oracle configuration knowledge, with security administration skills.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Unix was originally created as a single-user system.
2. True or False? Unix security has a long tradition, and though many concepts of the earliest Unix systems still apply, a large number of changes have taken place that fundamentally altered the way the operating system implements these security principles.
3. True or False? Achieving a high level of system security for the Unix system is a complex process that involves technical, operational, and managerial aspects of system operation.
4. True or False? For any interactive session, Linux systems require the user to log into the system.

5. True or False? The superuser has almost unlimited power on a Unix system, which can be a significant problem.

Multiple Choice

1. When a user is granted access to resources on a computing system, it is of vital importance to establish and verify the identity of the requesting entity. This process is commonly referred to as:
   - **A.** authorization.
   - **B.** availability.
   - **C.** integrity.
   - **D.** authentication.
   - **E.** confidentiality.
2. What allows for the loading of additional drivers for file systems?
   - **A.** File access
   - **B.** Identity-based access control
   - **C.** Filesystems in user space
   - **D.** Access control list
   - **E.** Meta data
3. The login process is a system daemon that is responsible for coordinating authentication and process setup for interactive users. To do this, the login process does the following, except which one?
   - **A.** Draw or display the login screen.
   - **B.** Collect the credential.
   - **C.** Present the user credential to only one of the configured user databases (typically, these can be files, NIS, Kerberos servers, or LDAP directories) for authentication.
   - **D.** Create a process with the user's default command-line shell, with the home directory as working directory.
   - **E.** Execute systemwide, user, and shell-specific start-up scripts.
4. What was introduced to simplify the administration of small groups of computers?
   - **A.** Systemauth PAM
   - **B.** Network Information System
   - **C.** Noninteractive access
   - **D.** Trusted hosts
   - **E.** Trusted networks
5. The most sensible alternative to the traditional interactive session protocols such as Telnet is the:
   - **A.** open-source package OpenSSH.
   - **B.** SSH daemon.
   - **C.** Secure Shell (SSH) system.
   - **D.** SSH protocol.
   - **E.** SSH-enabled file transfer program.

EXERCISE

Problem

On a Tuesday morning, a company support team was alerted by a customer who was trying to download a drive update. The customer reported that the FTP server was not responding to connection attempts. Upon failing to log in to the FTP server remotely via the secure shell, the support team member walked to a server room only to discover that the machine crashed and was not able to boot. The reason was simple: No operating system was found. The company gathered the standard set of network servers (all running some version of Unix or Linux): Web, email, DNS servers, and also a dedicated FTP server, used to distribute hardware drivers for the company inventory. In this case project, how would the company go about implementing an incident response plan?

Hands-On Projects

Project

Despite the risks of viruses and malicious attacks, most Linux Web servers are inadequately protected against intrusion. How would a company go about protecting their Linux Web servers against intrusion?

Case Projects

Problem

Rlogin is a software utility for Unix-like computer operating systems that allows users to log in on another host via a network, communicating via TCP port 513. Rlogin is most commonly deployed on corporate or academic networks, where user account information is shared between all the Unix machines on the network (often using NIS). But rlogin does have serious security problems. Please list rlogin's possible security problems.

Optional Team Case Project

Problem

Brute-force attacks against remote services such as SSH, FTP, and telnet are still the most common form of attack to compromise servers facing the Internet. So, how would security administrators go about thwarting these types of attack?

Eliminating the Security Weakness of Linux and Unix Operating Systems

Mario Santana
Terremark

1. INTRODUCTION TO LINUX AND UNIX

A simple Google search for define:unix yields many definitions. This definition comes from Microsoft: "A powerful multitasking operating system developed in 1969 for use in a minicomputer environment; still a widely used network operating system."[1]

What is Unix?

Unix is many things. Officially, it is a brand and an operating system specification. In common usage, the word *Unix* is often used to refer to one or more of many operating systems that derive from or are similar to the operating system designed and implemented about 41 years ago at AT & T Bell Laboratories. Throughout this chapter, we'll use the term *Unix* to include official Unix-branded operating systems as well as Unix-like operating systems such as BSD, Linux, and even Macintosh OS X.

History

Years after AT & T's original implementation, there followed decades of aggressive market wars among many operating system vendors, each claiming that its operating system was Unix. The ever-increasing incompatibilities between these different versions of Unix were seen as a major deterrent to the marketing and sales of Unix. As personal computers grew more powerful and flexible, running inexpensive operating systems like Microsoft Windows and IBM OS/2, they threatened Unix as the server platform of choice. In response to these and other marketplace pressures, most major Unix vendors eventually backed efforts to standardize the Unix operating system.

Unix Is a Brand

Since the early 1990s, the Unix brand has been owned by The Open Group. This organization manages a set of specifications with which vendors must comply to use the Unix brand in referring to their operating system products. In this way, The Open Group provides a guarantee to the marketplace that any system labeled as Unix conforms to a strict set of standards.

Unix Is a Specification

The Open Group's standard is called the Single Unix Specification. It is created in collaboration with the Institute of Electrical and Electronics Engineers (IEEE), the International Standards Organization (ISO), and others. The specification is developed, refined, and updated in an open, transparent process.

The Single Unix Specification comprises several components, covering core system interfaces such as system calls as well as commands, utilities, and a development environment based on the C programming language. Together, these describe a "functional superset of consensus-based specifications and historical practice."[2]

Lineage

The phrase *historical practice* in the description of the Single Unix Specification refers to the many operating systems historically referring to themselves as Unix. These include everything from AT & T's original releases to the versions released by the University of California at Berkeley and major commercial offerings by the likes of IBM, Sun, Digital Equipment Corporation (DEC), Hewlett-Packard (HP), the Santa Cruz Operation (SCO),

Novell, and even Microsoft. But any list of Unix operating systems would be incomplete if it didn't mention Linux (see Figure 10.1).

What is Linux?

Linux is a bit of an oddball in the Unix operating system lineup. That's because, unlike the Unix versions released by the major vendors, Linux did not reuse any existing source code. Instead, Linux was developed from scratch by a Finnish university student named Linus Torvalds.

Most Popular Unix-like OS

Linux was written from the start to function very similarly to existing Unix products. And because Torvalds worked on Linux as a hobby, with no intention of making money, it was distributed for free. These factors and others contributed to making Linux the most popular Unix operating system today.

Linux Is a Kernel

Strictly speaking, Torvalds's pet project has provided only one part of a fully functional Unix operating system: the kernel. The other parts of the operating system, including the commands, utilities, development environment, desktop environment, and other aspects of a full Unix operating system, are provided by other parties, including GNU, XOrg, and others.

Linux is a Community

Perhaps the most fundamentally different thing about Linux is the process by which it is developed and improved. As the hobby project that it was, Linux was released by Torvalds on the Internet in the hopes that someone out there might find it interesting. A few programmers saw Torvalds's hobby kernel and began working on it for fun, adding features and fleshing out functionality in a sort of unofficial partnership with Torvalds. At this point, everyone was just having fun, tinkering with interesting concepts. As more and more people joined the unofficial club, Torvalds's pet project ballooned into a worldwide phenomenon.

Today, Linux is developed and maintained by hundreds of thousands of contributors all over the world. In 1996, Eric S. Raymond[3] famously described the distributed development methodology used by Linux as a bazaar—a wild, uproarious collection of people, each developing whatever feature they most wanted in an operating system, or improving whatever shortcoming most impacted them. Yet somehow, this quick-moving community resulted in a development process that was stable as a whole and that produced an amazing amount of progress in a very short time.

This is radically different from the way in which Unix systems have typically been developed. If the Linux community is like a bazaar, then other Unix systems can be described as a cathedral—carefully preplanned and painstakingly assembled over a long period of time, according to specifications handed down by master architects from previous generations. Recently, however, some of the traditional Unix vendors have started moving toward a more decentralized, bazaar-like development model similar in many ways to the Linux methodology.

Linux Is Distributions

The open-source movement in general is very important to the success of Linux. Thanks to GNU, XOrg, and other open-source contributors, there was an almost complete Unix already available when the Linux kernel was released. Linux only filled in the final missing component of a no-cost, open-source Unix. Because the majority of the other parts of the operating system came from the GNU project, Linux is also known as GNU/Linux.

To actually install and run Linux, it is necessary to collect all the other operating system components. Because of the interdependency of the operating system components—each component must be compatible with the others—it is important to gather the right versions of all these components. In the early days of Linux, this was quite a challenge!

Soon, however, someone gathered up a self-consistent set of components and made them all available from a central download location. The first such efforts include H. J. Lu's "boot/root" floppies and MCC Interim Linux. These folks did not necessarily develop any of these components; they only redistributed them in a more convenient package. Other people did the same, releasing new bundles called *distributions* whenever a major upgrade was available.

Some distributions touted the latest in hardware support; others specialized in mathematics or graphics or another type of computing; still others built a distribution that would provide the simplest or most attractive user experience. Over time, distributions have become more robust, offering important features such as package management, which allows a user to safely upgrade parts of the system without reinstalling everything else.

Linux Standard Base

Today there are dozens of Linux distributions. Different flavors of distributions have evolved over the years. A primary distinguishing feature is the package management

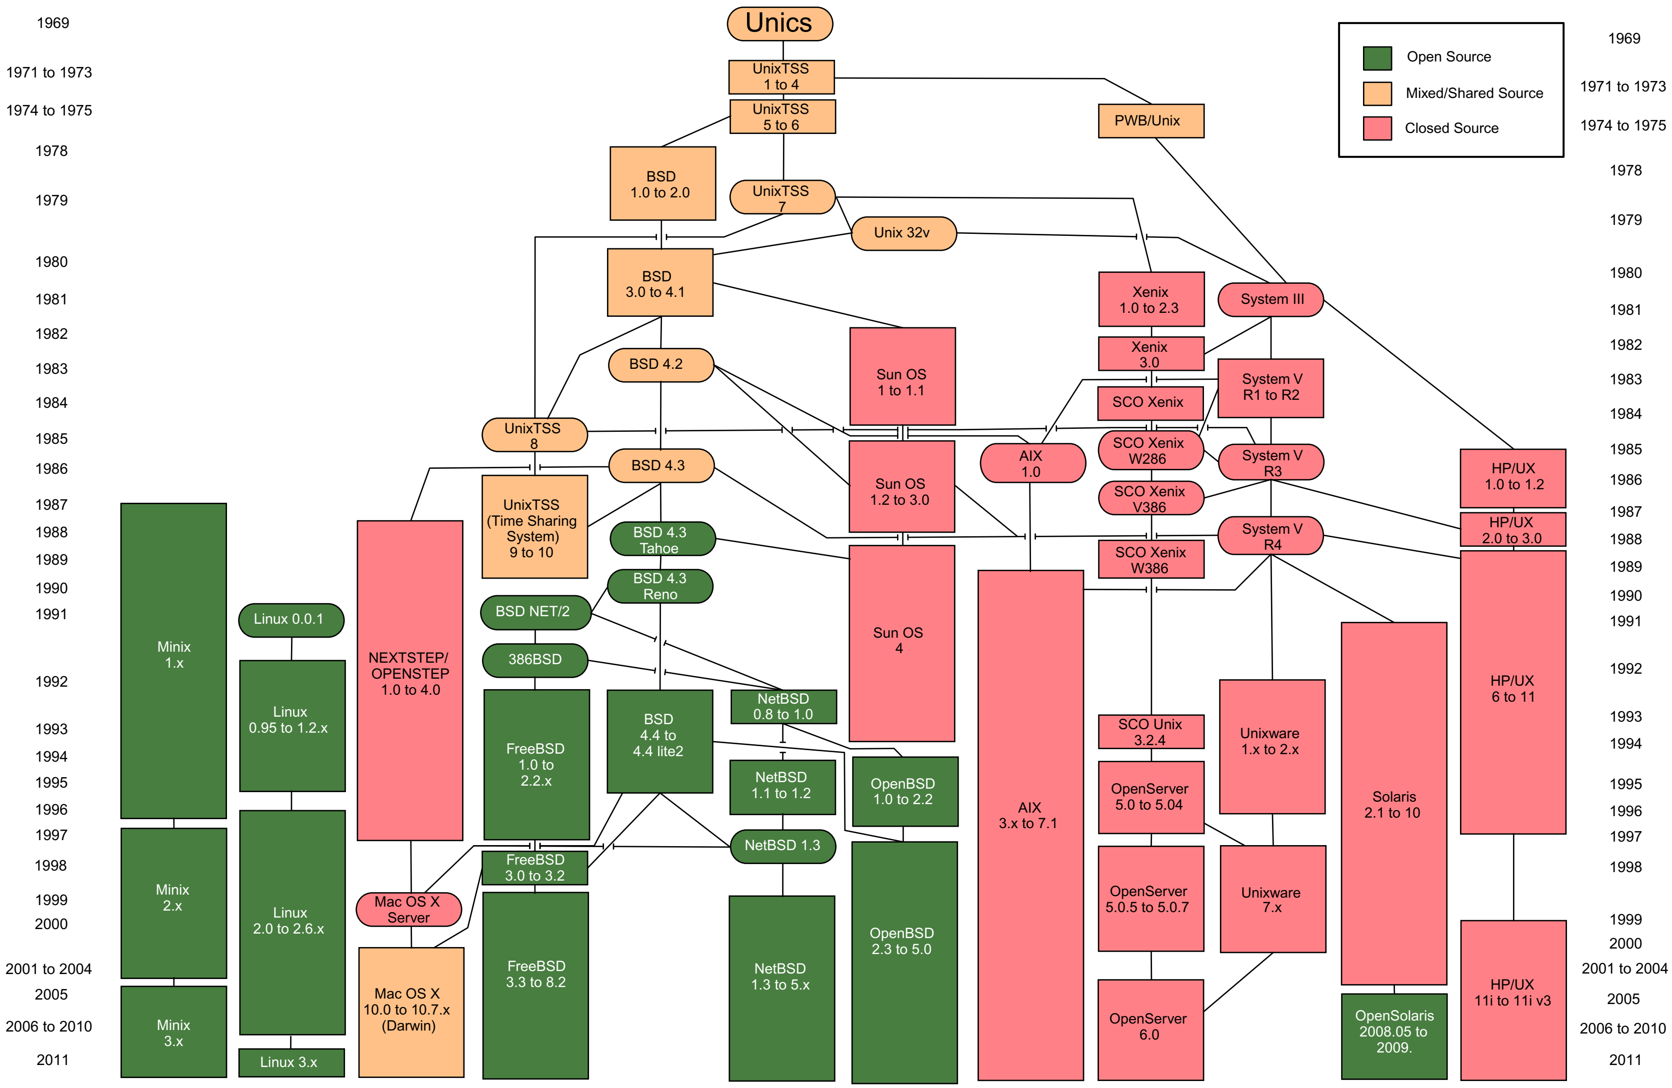

FIGURE 10.1 The simplified Unix family tree presents a timeline of some of today's most successful Unix variants.

system. Some distributions are primarily volunteer community efforts; others are commercial offerings. See Figure 10.2 for a timeline of Linux development.

The explosion in the number of different Linux distributions created a situation reminiscent of the Unix wars of previous decades. To address this issue, the Linux Standard Base was created to specify certain key standards of behavior for conforming Linux distributions. Most major distributions comply with the Linux Standard Base specifications.

A Word of Warning

Understanding the history and lineage of Unix is important for several reasons. First, it gives us insight into why some things work the way they do—often it's for historical reasons. Second, the wide variety of versions allows us to choose one that best fits our needs for security, functionality, performance, and compatibility. Finally, and most importantly, this understanding shows us that the rich history and many flavors of Unix make it impossible to treat security as a recipe. Similarly, this chapter cannot possibly cover all the details of every variation of the Unix commands that we will introduce.

Instead of memorizing some steps that will harden a Unix system, we must understand the underlying concepts and the overarching architecture, and be willing to adapt our knowledge to the particular details of whatever version we're working with. Keep this in mind as you read this chapter, especially as you apply the lessons in it.

System Architecture

The architecture of Unix operating systems is relatively simple. The kernel interfaces with hardware and provides core functionality for the system. File systems provide permanent storage and access to many other kinds of functionality. Processes embody programs as their instructions are being executed. Permissions describe the actions that users may take on files and other resources.

Kernel

The operating system kernel manages many of the fundamental details that an operating system needs to deal with, including memory, disk storage, and low-level networking. In general, the kernel is the part of the operating system that talks directly to hardware; it presents an abstracted interface to the rest of the operating system components.

Because the kernel understands all the different sorts of hardware that the operating system deals with, the rest of the operating system is freed from needing to understand all those underlying details. The abstracted interface presented by the kernel allows other parts of the operating

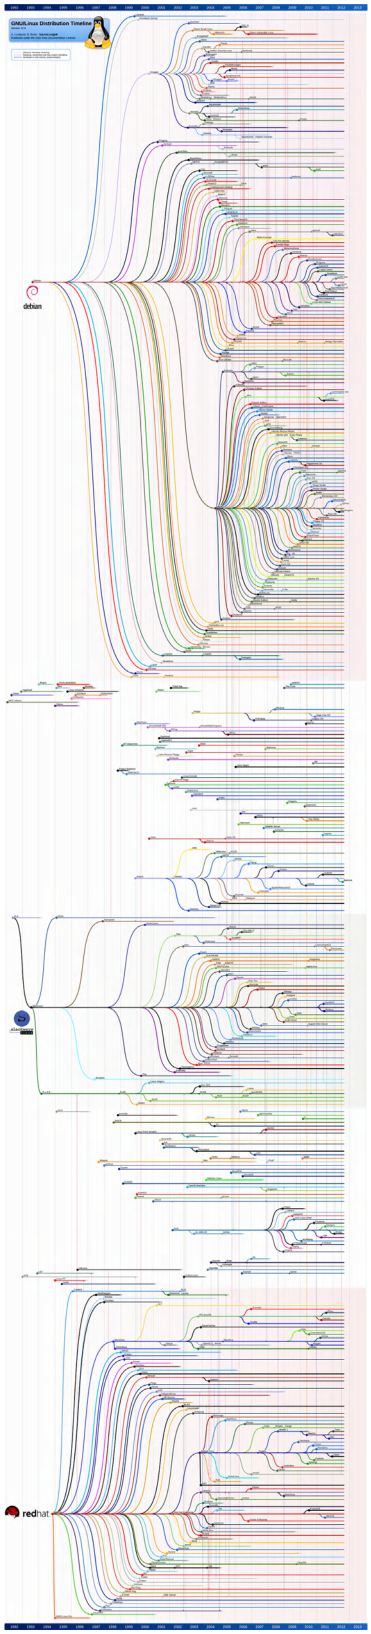

FIGURE 10.2 History of Linux distributions.

system to read and write files or communicate on the network without knowing or caring about what kinds of disks or network adapter are installed.

File System

A fundamental aspect of Unix is its file system. Unix pioneered the hierarchical model of directories that contain files and/or other directories to allow the organization of data into a tree structure. Multiple file systems could be accessed by connecting them to empty directories in the root file system. In essence, this is very much like grafting one hierarchy onto an unused branch of another. There is no limit to the number of file systems that can be mounted in this way.

The file system hierarchy is also used to provide more than just access to and organization of local files. Network data shares can also be mounted, just like file systems on local disks. And special files such as device files, first in/first out (FIFO) or pipe files, and others give direct access to hardware or other system features.

Users and Groups

Unix was designed to be a time-sharing system and as such has been a multiuser since its inception. Users are identified in Unix by their usernames, but internally each is represented as a unique identifying integer called a *user ID*, or *UID*. Each user can also belong to one or more groups. Like users, groups are identified by their names, but they are represented internally as a unique integer called a *group ID*, or *GID*. Each file or directory in a Unix file system is associated with a user and a group.

Permissions

Unix has traditionally had a simple permissions architecture, based on the user and group associated with files in the file system. This scheme makes it possible to specify read, write, and/or execute permissions, along with a special permission setting whose effect is context-dependent. Furthermore, it's possible to set these permissions independently for the file's owner; the file's group, in which case the permission applies to all users, other than the owner, who are members of that group, and to all other users. The chmod command is used to set the permissions by adding up the values of all desired permission types, as shown in Table 10.1.

The Unix permission architecture has historically been the target of criticism for its simplicity and inflexibility. It is not possible, for example, to specify a different permission setting for more than one user or more than one group. These limitations have been addressed in more recent file system implementations using extended file attributes and access control lists.

TABLE 10.1 Unix Permissions and Chmod.

Chmod Usage	Read	Write	Execute	Special
User	u + r or 0004	u + w or 0002	u + x or 0001	u + s or 4000
Group	u + r or 0040	u + w or 0020	u + x or 0010	u + s or 2000
Other	u + r or 0400	u + w or 0200	u + x or 0100	u + s or 1000

Processes

When a program is executed, it is represented in a Unix system as a process. The kernel keeps track of many pieces of information about each process. This information is required for basic housekeeping and advanced tasks such as tracing and debugging. This information represents the user, group, and other data used for making security decisions about a process's access rights to files and other resources.

2. HARDENING LINUX AND UNIX

With a basic understanding of the fundamental concepts of the Unix architecture, let's take a look at the practical work of securing a Unix deployment. First, we'll review considerations for securing Unix machines from network-borne attacks. Then we'll look at security from a host-based perspective. Finally, we'll talk about systems management and how different ways of administering a Unix system can impact security.

Network Hardening

Defending from network-borne attacks is arguably the most important aspect of Unix security. Unix machines are used heavily to provide network-based services, running Web sites, domain name server (DNS), firewalls, and many more. To provide these services, Unix systems must be connected to hostile networks, such as the Internet, where legitimate users can easily access and make use of these services.

Unfortunately, providing easy access to legitimate users makes the system readily accessible to bad actors who would subvert access controls and other security measures to steal sensitive information, change reference data, or simply make services unavailable to legitimate users. Attackers can probe systems for security weaknesses, identify and exploit vulnerabilities, and generally wreak digital havoc with relative impunity from anywhere around the globe.

Minimizing Attack Surface

Every way in which an attacker can interact with the system poses a security risk. Any system that makes available a large number of network services, especially complex services such as the custom Web applications of today, suffers a higher likelihood that inadequate permissions or a software bug or some other error will present attackers with an opportunity to compromise security. In contrast, even a very insecure service cannot be compromised if it is not running.

A pillar of any security architecture is the concept of minimizing the attack surface. By reducing the number of enabled network services and the available functionality of those services that are enabled, a system presents a smaller set of functions that can be subverted by an attacker. Other ways to reduce attackable surface areas are to deny network access from unknown hosts when possible and to limit the privileges of running services in order to minimize the damage they might be subverted to cause.

Eliminate Unnecessary Services

The first step in reducing an attack surface is to disable unnecessary services provided by a server. In Unix, services are enabled in one of several ways. The "Internet daemon," or *inetd*, is a historically popular mechanism for managing network services. Like many Unix programs, inetd is configured by editing a text file. In the case of inetd, this text file is /etc/inetd.conf; unnecessary services should be commented out of this file. Today a more modular replacement for inetd, called *xinetd*, is gaining popularity. The configuration for xinetd is not contained in any single file but in many files located in the /etc/xinetd.d/ directory. Each file in this directory configures a single service, and a service may be disabled by removing the file or by making the appropriate changes to the file.

Many Unix services are not managed by inetd or xinetd, however. Network services are often started by the system's initialization scripts during the boot sequence. Derivatives of the BSD Unix family historically used a simple initialization script located in /etc/rc. To control the services that are started during the boot sequence, it is necessary to edit this script.

Recent Unices (the plural of Unix), even BSD derivatives, use something similar to the initialization scheme of the System V or higher family. In this scheme, a "run level" is chosen at boot time. The default run level is defined in /etc/inittab; typically, it is 3 or 5. The initialization scripts for each run level are located in /etc/rc *X*. d, where *X* represents the run-level number. The services that are started during the boot process are controlled by adding or removing scripts in the appropriate run-level directory. Some Unices provide tools to help manage these scripts, such as the rcconf command in Debian and derivatives or the chkconfig command in Red Hat Linux and derivatives. Other methods of managing services in Unix include the Service Management Facility of Solaris 10 or higher. No matter how a network service is started or managed, however, it must necessarily listen for network connections to make itself available to users. This fact makes it possible to positively identify all running network services by looking for processes that are listening for network connections. Almost all versions of Unix provide a command that makes this a trivial task. The netstat command can be used to list various kinds of information about the network environment of a Unix host. Running this command with the appropriate flags (usually −lut) will produce a listing of all open network ports, including those that are listening for incoming connections (see Figure 10.3).

Finally, let's take a brief look at how services that are necessary can be configured securely. The following checklist (see checklist: An Agenda for Action When Securing Web Server Activities) presents several points to consider when securing a Web server.

Securely Configure Necessary Services

Every such listening port should correspond to a necessary service that is well understood and securely configured. Although we cannot cover every service that might be run on a Unix system, we'll explore a few of the more common services.

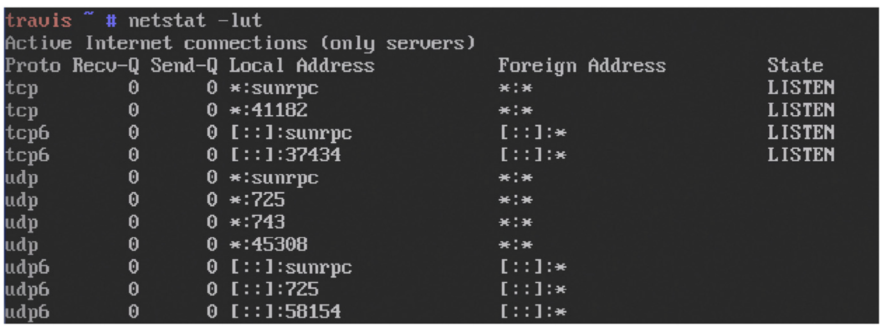

FIGURE 10.3 Output of netstat −lut.

An Agenda for Action when Securing Web Server Activities

The following items are possible actions that organizations should consider; some of the items may not apply to all organizations. Some important points to consider when securing Apache or any other Web server include[4] (check all tasks completed):

_____**1.** Keep up to date with server software updates.

_____**2.** Mitigate denial-of-service attacks by maximizing performance and limiting the resources consumed.

_____**3.** Minimize permissions on Web content directories and files.

_____**4.** Minimize capabilities for dynamic content.

_____**5.** When dynamic content (Web applications) is necessary, carefully check the security of the dynamic content scripts.

_____**6.** Monitor server logs for malicious or anomalous activity.

One of the most popular services to run on a Unix system is a Web server. The Apache Web server is one of the most popular because it is free, powerful, and flexible, with many third-party add-ons to make it even more powerful and flexible. All this power and flexibility can also make secure Apache configuration a nontrivial exercise.

Another popular service on Unix servers is the Secure Shell service, or SSH. This service enables secure remote access to the Unix console. To configure it for maximum security, disable the use of passwords and require private key authentication. SSH also allows an administrator to strictly limit which commands can be executed by a given account—a feature that can minimize the risk of SSH accounts used for automated or centralized management functions.

Unix systems are often used to run database software. These databases can contain sensitive information, in which case they must be carefully configured to secure that data; however, even when the data is of little value, the database server itself can be used as a stepping stone in a larger compromise. That's one reason why it's important to secure any Unix system and the services it runs. There are many different kinds of database software, and each one must be hardened according to its own unique capabilities. From the Unix point of view, however, the security of any database can be greatly enhanced by using one of the firewall technologies described below to limit which remote hosts can access the database software.

Host-based

Obviously, it is impossible to disable all the services provided by a server. However, it is possible to limit the hosts that have access to a given service. Often it is possible to identify a well-defined list of hosts or subnets that should be granted access to a network service. There are several ways in which this restriction can be configured.

A classical way of configuring these limitations is through the *tcpwrappers* interface. The tcpwrappers functionality is to limit the network hosts that are allowed to access services provided by the server. These controls are configured in two text files, /etc/hosts. allow and /etc/hosts.deny. This interface was originally designed to be used by inetd and xinetd on behalf of the services they manage. Today most service-providing software directly supports this functionality.

Another, more robust method of controlling network access is through firewall configurations. Most modern Unices include some form of firewall capability: IPFilter, used by many commercial Unices; IPFW, used by most of the BSD variants; and IPTables, used by Linux. In all cases, the best way to arrive at a secure configuration is to create a default rule to deny all traffic and then to create the fewest, most specific exceptions possible.

Modern firewall implementations are able to analyze every aspect of the network traffic they filter as well as aggregate traffic into logical connections and track the state of those connections. The ability to accept or deny connections based on more than just the originating network address and to end a conversation when certain conditions are met makes modern firewalls a much more powerful control for limiting attack surface than tcpwrappers.

Chroot and Other Jails

Eventually, some network hosts must be allowed to access a service if it is to be useful at all. In fact, it is often necessary to allow anyone on the Internet to access a service, such as a public Web site. Once a malicious user can access a service, there is a risk that the service will be subverted into executing unauthorized instructions on behalf of the attacker. The potential for damage is limited only by the permissions that the service process has to access resources and to make changes on the system. For this reason, an important security measure is to limit the power of a service to the bare minimum necessary to allow it to perform its duties.

A primary method of achieving this goal is to associate the service process with a user who has limited permissions. In many cases, it's possible to configure a user with very few permissions on the system and to associate that user with a service process. In these cases, the service

4. Apache.org, "Security Tips," retrieved August 22, 2012 from http://httpd.apache.org/docs/2.4/misc/security_tips.html.

can only perform a limited amount of damage, even if it is subverted by attackers.

Unfortunately, this is not always very effective or even possible. A service must often access sensitive server resources to perform its work. Configuring a set of permissions to allow access to only the sensitive information required for a service to operate can be complex or impossible.

In answer to this challenge, Unix has long supported the chroot and ulimit interfaces as ways to limit the access that a powerful process has on a system. The chroot interface limits a process's access on the file system. Regardless of actual permissions, a process run under a chroot jail can only access a certain part of the file system. Common practice is to run sensitive or powerful services in a chroot jail and make a copy of only those file system resources that the service needs in order to operate. This allows a service to run with a high level of system access, yet be unable to damage the contents of the file system outside the portion it is allocated.[5]

The ulimit interface is somewhat different in that it can configure limits on the amount of system resources a process or user may consume. A limited amount of disk space, memory, CPU utilization, and other resources can be set for a service process. This can curtail the possibility of a denial-of-service attack because the service cannot exhaust all system resources, even if it has been subverted by an attacker.[6]

Access Control

Reducing the attack surface area of a system limits the ways in which an attacker can interact and therefore subvert a server. Access control can be seen as another way to reduce the attack surface area. By requiring all users to prove their identity before making any use of a service, access control reduces the number of ways in which an anonymous attacker can interact with the system.

In general, access control involves three phases. The first phase is identification, where a user asserts his identity. The second phase is authentication, where the user proves his identity. The third phase is authorization, where the server allows or disallows particular actions based on permissions assigned to the authenticated user.

Strong Authentication

It is critical, therefore, that a secure mechanism is used to prove the user's identity. If this mechanism were to be subverted, an attacker would be able to impersonate a user to access resources or issue commands with whatever authorization level has been granted to that user. For decades, the primary form of authentication has been through the use of passwords. However, passwords suffer from several weaknesses as a form of authentication, presenting attackers with opportunities to impersonate legitimate users for illegitimate ends. Bruce Schneier has argued for years that "passwords have outlived their usefulness as a serious security device."[7] More secure authentication mechanisms include two-factor authentication and PKI certificates.

Two-Factor Authentication

Two-factor authentication involves the presentation of two of the following types of information by users to prove their identity: something they know, something they have, or something they are. The first factor, something they know, is typified by a password or a PIN—some shared secret that only the legitimate user should know. The second factor, something they have, is usually fulfilled by a unique physical token (see Figure 10.4). RSA makes a popular line of such tokens, but cell phones, matrix cards, and other alternatives are becoming more common. The third factor, something they are, usually refers to biometrics.

Unix supports various ways to implement two-factor authentication into the system. Pluggable Authentication Modules, or PAMs, allow a program to use arbitrary authentication mechanisms without needing to manage any of the details. PAMs are used by Solaris, Linux, and other Unices. BSD authentication serves a similar purpose and is used by several major BSD derivatives.

With PAM or BSD authentication, it is possible to configure any combination of authentication mechanisms, including simple passwords, biometrics, RSA tokens, Kerberos, and more. It's also possible to configure a different combination for different services. This kind of flexibility allows a Unix security administrator to implement a very strong authentication requirement as a prerequisite for access to sensitive services.

PKI

Strong authentication can also be implemented using a Private Key Infrastructure (PKI). Secure Socket Layer (SSL), is a simplified PKI designed for secure communications, familiar from its use in securing traffic on the Web. Through use of a similar foundation of technologies, it's possible to issue and manage certificates to authenticate users rather than Web sites. Additional technologies, such as a trusted platform module or a smart

FIGURE 10.4 Physical tokens used for two-factor authentication.

card, simplify the use of these certificates in support of two-factor authentication.

Dedicated Service Accounts

After strong authentication, limiting the complexity of the authorization phase is the most important part of access control. User accounts should not be authorized to perform sensitive tasks. Services should be associated with dedicated user accounts, which should then be authorized to perform only those tasks required for providing that service.

Additional Controls

In addition to minimizing the attack surface area and implementing strong access controls, there are several important aspects of securing a Unix network server.

Encrypted Communications

One of the ways an attacker can steal sensitive information is to eavesdrop on network traffic. Information is vulnerable as it flows across the network, unless it is encrypted. Sensitive information, including passwords and intellectual property, are routinely transmitted over the network. Even information that is seemingly useless to an attacker can contain important clues to help a bad actor compromise security.

File Transfer Protocol (FTP), World Wide Web (WWW), and many other services that transmit information over the network support the Secure Sockets Layer (SSL) standard for encrypted communications. For server software that doesn't support SSL natively, wrappers like *stunnel* provide transparent SSL functionality.

No discussion of Unix network encryption can be complete without mention of Secure Shell, or SSH. SSH is a replacement for Telnet and RSH, providing remote command-line access to Unix systems as well as other functionality. SSH encrypts all network communications using SSL, mitigating many of the risks of Telnet and RSH.

Log Analysis

In addition to encrypting network communications, it is important to keep a detailed activity log to provide an audit trail in case of anomalous behavior. At a minimum, the logs should capture system activity such as logon and logoff events as well as service program activity, such as FTP, WWW, or Structured Query Language (SQL) logs.

Since the 1980s, the *syslog* service has been used to manage log entries in Unix. Over the years, the original implementation has been replaced by more feature-rich implementations, such as *syslog-ng* and *rsyslog*. These systems can be configured to send log messages to local files as well as remote destinations, based on independently defined verbosity levels and message sources.

The syslog system can independently route messages based on the facility, or message source, and the level, or message importance. The facility can identify the message as pertaining to the kernel, the email system, user

activity, an authentication event, or any of various other services. The level denotes the criticality of the message and can typically be one of *emergency, alert, critical, error, warning, notice, informational*, and *debug*. Under Linux, the *klog* process is responsible for handling log messages generated by the kernel; typically, klog is configured to route these messages through syslog, just like any other process.

Some services, such as the Apache Web server, have limited or no support for syslog. These services typically include the ability to log activity to a file independently. In these cases, simple scripts can redirect the contents of these files to syslog for further distribution and/or processing.

Relevant logs should be copied to a remote, secure server to ensure that they cannot be tampered with. Additionally, file hashes should be used to identify any attempt to tamper with the logs. In this way, the audit trail provided by the log files can be depended on as a source of uncompromised information about the security status of the system.

IDS/IPS

Intrusion detection systems (IDSs) and intrusion prevention systems (IPSs) have become commonplace security items on today's networks. Unix has a rich heritage of such software, including Snort, Prelude, and OSSEC. Correctly deployed, an IDS can provide an early warning of probes and other precursors to attack.

Host Hardening

Unfortunately, not all attacks originate from the network. Malicious users often gain access to a system through legitimate means, bypassing network-based defenses. Various steps can be taken to harden a Unix system from a host-based attack such as this.

Permissions

The most obvious step is to limit the permissions of user accounts on the Unix host. Recall that every file and directory in a Unix file system is associated with a single user and a single group. User accounts should each have permissions that allow full control of their respective home directories. Together with permissions to read and execute system programs, this allows most of the typical functionality required of a Unix user account. Additional permissions that might be required include mail spool files and directories as well as crontab files for scheduling tasks.

Administrative Accounts

Setting permissions for administrative users is a more complicated question. These accounts must access very powerful system-level commands and resources in the routine discharge of their administrative functions. For this reason, it's difficult to limit the tasks these users may perform. It's possible, however, to create specialized administrative user accounts, then authorize these accounts to access a well-defined subset of administrative resources. Printer management, Web site administration, email management, database administration, storage management, backup administration, software upgrades, and other specific administrative functions common to Unix systems lend themselves to this approach.

Groups

Often it is convenient to apply permissions to a set of users rather than a single user or all users. The Unix group mechanism allows for a single user to belong to one or more groups and for file system permissions and other access controls to be applied to a group.

File System Attributes and ACLs

It can become unfeasibly complex to implement and manage anything more than a simple permissions scheme using the classical Unix file system permission capabilities. To overcome this issue, modern Unix file systems support access control lists, or ACLs. Most Unix file systems support ACLs using extended attributes that could be used to store arbitrary information about any given file or directory. By recognizing authorization information in these extended attributes, the file system implements a comprehensive mechanism to specify arbitrarily complex permissions for any file system resource.

ACLs contain a list of *access control entries*, or ACEs, which specify the permissions that a user or group has on the file system resource in question. On most Unices, the chacl command is used to view and set the ACEs of a given file or directory. The ACL support in modern Unix file systems provides a fine-grained mechanism for managing complex permissions requirements. ACLs do not make the setting of minimum permissions a trivial matter, but complex scenarios can now be addressed effectively.

Intrusion Detection

Even after hardening a Unix system with restrictive user permissions and ACLs, it's important to maintain logs of system activity. As with activity logs of network services, host-centric activity logs track security-relevant events that could show symptoms of compromise or evidence of attacks in the reconnaissance or planning stages.

Audit Trails

Again, as with network activity logs, Unix has leaned heavily on syslog to collect, organize, distribute, and store log messages about system activity. Configuring syslog for

system messages is the same as for network service messages. The kernel's messages, including those messages generated on behalf of the kernel by klogd under Linux, are especially relevant from a hostcentric point of view.

An additional source of audit trail data about system activity is the history logs kept by a login shell such as *bash*. These logs record every command the user issued at the command line. The bash shell and others can be configured to keep these logs in a secure location and to attach timestamps to each log entry. This information is invaluable in identifying malicious activity, both as it is happening and after the fact.

File Changes

Besides tracking activity logs, monitoring file changes can be a valuable indicator of suspicious system activity. Attackers often modify system files to elevate privileges, capture passwords or other credentials, establish backdoors to ensure future access to the system, and support other illegitimate uses. Identifying these changes early can often foil an attack in progress before the attacker is able to cause significant damage or loss.

Programs such as Tripwire and Aide have been around for decades; their function is to monitor the file system for unauthorized changes and raise an alert when one is found. Historically, they functioned by scanning the file system and generating a unique *hash*, or fingerprint, of each file. On future runs, the tool would recalculate the hashes and identify changed files by the difference in the hash. Limitations of this approach include the need to regularly scan the entire file system, which can be a slow operation, as well as the need to secure the database of file hashes from tampering.

Today many Unix systems support file change monitoring: Linux has dnotify and inotify; Mac OS X has FSEvents, and other Unices have File Alteration Monitor. All these present an alternative method of identifying file changes and reviewing them for security implications.

Specialized Hardening

Many Unices have specialized hardening features that make it more difficult to exploit software vulnerabilities or to do so without leaving traces on the system and/or to show that the system is so hardened. Linux has been a popular platform for research in this area; even the National Security Agency (NSA) has released code to implement its strict security requirements under Linux. Here we outline two of the most popular Linux hardening packages. Other such packages exist for Linux and other Unices, some of which use innovative techniques such as virtualization to isolate sensitive data, but they are not covered here.

GRSec/PAX

The grsecurity package provides several major security enhancements for Linux. Perhaps the primary benefit is the flexible policies that define fine-grained permissions it can control. This role-based access control capability is especially powerful when coupled with grsecurity's ability to monitor system activity over a period of time and generate a minimum set of privileges for all users. Additionally, through the PAX subsystem, grsecurity manipulates program memory to make it very difficult to exploit many kinds of security vulnerabilities. Other benefits include a very robust auditing capability and other features that strengthen existing security features, such as chroot jails.

SELinux

Security Enhanced Linux, or SELinux, is a package developed by the NSA. It adds mandatory access control, or MAC, and related concepts to Linux. MAC involves assigning security attributes as well as system resources such as files and memory to users. When a user attempts to read, write, execute, or perform any other action on a system resource, the security attributes of the user and the resource are both used to determine whether the action is allowed, according to the security policies configured for the system. (See Figure 10.5.[8])

Systems Management Security

After hardening,a Unix host from network-borne attacks and hardening it from attacks performed by an authorized user of the machine, we will take a look at a few systems management issues. These topics arguably fall outside the purview of security as such; however, by taking certain considerations into account, systems management can both improve and simplify the work of securing a Unix system.

Account Management

User accounts can be thought of as keys to the "castle" of a system. As users require access to the system, they must be issued keys, or accounts, so they can use it. When a user no longer requires access to the system, her key should be taken away or at least disabled.

This sounds simple in theory, but account management in practice is anything but trivial. In all but the smallest environments, it is infeasible to manage user accounts without a centralized account directory where necessary changes can be made and propagated to every

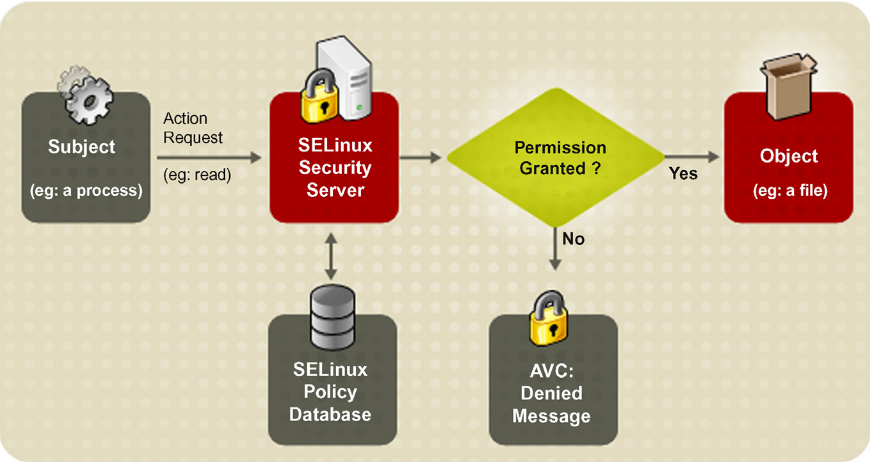

FIGURE 10.5 SELinux decision process.

server on the network. Through PAM, BSD authentication, and other mechanisms, modern Unices support LDAP, SQL databases, Windows NT and Active Directory, Kerberos, and myriad other centralized account directory technologies.

Patching

Outdated software is perhaps the number-one cause of easily preventable security incidents. Choosing a modern Unix with a robust upgrade mechanism and history of timely updates, at least for security fixes, makes it easier to keep software up to date and secure from well-known exploits. One of the main differentiating factors between the different Unix and Linux families is the software management and upgrade system. There are over 50 different package and upgrade management tools in use on the various Unix flavors.

Backups

When all else fails—especially when attackers have successfully modified or deleted data in ways that are difficult or impossible to positively identify—good backups will save the day. When backups are robust, reliable, and accessible, they put a ceiling on the amount of damage an attacker can do. Unfortunately, good backups don't help if the greatest damage comes from disclosure of sensitive information; in fact, backups could exacerbate the problem if they are not taken and stored in a secure way.

3. PROACTIVE DEFENSE FOR LINUX AND UNIX

As security professionals, we devote ourselves to defending systems from attack. However, it is important to understand the common tools, mind-sets, and motivations that drive attackers. This knowledge can prove invaluable in mounting an effective defense against attack. It's also important to prepare for the possibility of a successful attack and to consider organizational issues so that a secure environment can be developed.

Vulnerability Assessment

A vulnerability assessment looks for security weaknesses in a system. Assessments have become an established best practice, incorporated into many standards and regulations. They can be network-centric or host-based.

Network-based Assessment

Network-centric vulnerability assessment looks for security weaknesses a system presents to the network. Unix has a rich heritage of tools for performing network vulnerability assessments. Most of these tools are available on most Unix flavors.

Nmap is a free, open-source tool for identifying hosts on a network and the services running on those hosts. It's a powerful tool for mapping out the true services being provided on a network. It's also easy to get started with nmap.

Nessus is another free network security tool, though its source code isn't available. It's designed to check for and optionally verify the existence of known security vulnerabilities. It works by looking at various pieces of information about a host on the network, such as detailed version information about the operating system and any software providing services on the network. This information is compared to a database that lists vulnerabilities known to exist in certain software configurations. In many cases, Nessus is also capable of confirming a match in the vulnerability database by attempting an exploit; however, this is likely to crash the service or even the entire system. Many other tools are available for performing network vulnerability assessments. Insecure.Org, the

folks behind the nmap tool, also maintain a great list of security tools.[9]

Host-based Assessment

Several tools can examine the security settings of a system from a host-based perspective. These tools are designed to be run on the system that's being checked; no network connections are necessarily initiated. They check things such as file permissions and other insecure configuration settings on Unix systems.

One such tool, *lynis*, is available for various Linux distributions as well as some BSD variants. Another tool is the Linux Security Auditing Tool, or *lsat*. Ironically, lsat supports more versions of Unix than lynis does, including Solaris and AIX.

No discussion of host-based Unix security would be complete without mentioning *Bastille*. Although lynis and lsat are pure auditing tools that report on the status of various security-sensitive host configuration settings, Bastille was designed to help remediate these issues. Recent versions have a reporting-only mode that makes Bastille work like a pure auditing tool.

Incident Response Preparation

Regardless of how hardened a Unix system is, there is always a possibility that an attacker—whether it's a worm, a virus, or a sophisticated custom attack—will successfully compromise the security of the system. For this reason, it is important to think about how to respond to a wide variety of security incidents.

Predefined Roles and Contact List

A fundamental part of incident response preparation is to identify the roles that various personnel will play in the response scenario. The manual, hands-on gestalt of Unix systems administration has historically forced Unix systems administrators to be familiar with all aspects of the Unix systems they manage. These should clearly be on the incident response team. Database, application, backup, and other administrators should be on the team as well, at least as secondary personnel that can be called on as necessary.

Simple Message for End Users

Incident response is a complicated process that must deal with conflicting requirements to bring the systems back online while ensuring that any damage caused by the attack—as well as whatever security flaws were exploited to gain initial access—is corrected. Often, end users without incident response training are the first to handle a system after a security incident has been identified. It is important that these users have clear, simple instructions in this case, to avoid causing additional damage or loss of evidence. In most situations, it is appropriate to simply unplug a Unix system from the network as soon as a compromise of its security is confirmed. It should not be used, logged onto, logged off from, turned off, disconnected from electrical power, or otherwise tampered with in any way. This simple action has the best chance, in most cases, to preserve the status of the incident for further investigation while minimizing the damage that could ensue.

Blue Team/Red Team Exercises

Any incident response plan, no matter how well designed, must be practiced to be effective. Regularly exercising these plans and reviewing the results are important parts of incident response preparation. A common way of organizing such exercises is to assign some personnel (the Red Team) to simulate a successful attack, while other personnel (the Blue Team) are assigned to respond to that attack according to the established incident response plan. These exercises, referred to as Red Team/Blue Team exercises, are invaluable for testing incident response plans. They are also useful in discovering security weaknesses and in fostering a sense of *esprit des corps* among the personnel involved.

Organizational Considerations

Various organizational and personnel management issues can also impact the security of Unix systems. Unix is a complex operating system. Many different duties must be performed in the day-to-day administration of Unix systems. Security suffers when a single individual is responsible for many of these duties; however, that is commonly the skill set of Unix system administration personnel.

Separation of Duties

One way to counter the insecurity of this situation is to force different individuals to perform different duties. Often, simply identifying independent functions, such as backups and log monitoring, and assigning appropriate permissions to independent individuals is enough. Log management, application management, user management, system monitoring, and backup operations are just some of the roles that can be separated.

Forced Vacations

Especially when duties are appropriately separated, unannounced forced vacations are a powerful way to bring fresh perspectives to security tasks. It's also an effective deterrent to internal fraud or mismanagement of security

9. Insecure.Org, 2008, "Top 100 Network Security Tools," retrieved October 9, 2008, from http://sectools.org.

responsibilities. A more robust set of requirements for organizational security comes from the Information Security Management Maturity Model, including its concepts of transparency, partitioning, separation, rotation, and supervision of responsibilities.[10]

4. SUMMARY

This chapter provides the technical security policies, requirements, and implementation details for eliminating the security weaknesses of Linux and Unix operating systems. The chapter also contains general requirements for Linux and Unix operating systems, as well as specific requirements. This chapter may also be used as a guide for enhancing the security configuration of any Linux or Unix-like system. The chapter also contains all requirements, check, and fix procedures that are expected to be applicable to most Linux and Unix-like operating systems.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Unix is a brand and an operating system specification.
2. True or False? The architecture of Unix operating systems is relatively difficult.
3. True or False? Defending from network-borne attacks is arguably the least important aspect of Unix security.
4. True or False? The first step in reducing an attack surface is to disable unnecessary services provided by a server.
5. True or False? Every listening port should not correspond to a necessary service that is well understood and securely configured.

Multiple Choice

1. What can be seen as another way to reduce the attack surface area?
   A. Dedicated service accounts
   B. PKI
   C. Two-factor authentication
   D. Strong authentication
   E. Access control
2. Information is vulnerable as it flows across the network, unless it is:
   A. log analyzed.
   B. clear texted.
   C. basically authenticated.
   D. encrypted.
   E. All of the above
3. The Unix group mechanism allows for a single user to belong to one or more:
   A. attributes.
   B. ACLs.
   C. permissions.
   D. groups.
   E. focus groups.
4. Even after hardening a Unix system with restrictive user permissions and ACLs, it's important to maintain logs of:
   A. audit trails.
   B. system messages.
   C. system activity.
   D. bash.
   E. All of the above.
5. An additional source of audit trail data about system activity is the history logs kept by a login shell such as:
   A. log.
   B. file.
   C. password.
   D. bash.
   E. All of the above.

EXERCISE

Problem

Is Linux a secure operating system?

Hands-On Projects

Project

Is it more secure to compile driver support directly into the kernel, instead of making it a module?

Case Projects

Problem

Why does logging in as root from a remote machine always fail?

Optional Team Case Project

Problem

How do you enable shadow passwords on your Red Hat 4.2 or higher, or 5.x or higher Linux box?

Chapter 11

Internet Security

Jesse Walker
Intel Corporation

The Internet, with all its accompanying complications, is integral to our lives. The security problems besetting the Internet are legendary and have become daily annoyances—and worse—to many users. Given the Net's broad impact on our lives and the widespread security issues associated with it, it is worthwhile understanding what can be done to improve the immunity of our communications from attack.

The Internet can serve as a laboratory for studying network security issues; indeed, we can use it to study nearly every kind of security issue. We will pursue only a modest set of questions related to this theme. The goal of this chapter is to understand how cryptography can be used to address some of the security issues affecting communications protocols. To do so, it will be helpful to first understand the Internet architecture. After that we will survey the types of attacks that are possible against communications. With this background we will be able to understand how cryptography can be used to preserve the confidentiality and integrity of messages.

Our goal is modest: It is only to describe the network architecture and its cryptographic-based security mechanisms sufficiently to understand some of the major issues confronting security systems designers and to appreciate some of the major design decisions they have to make to address these issues.

1. INTERNET PROTOCOL ARCHITECTURE

The Internet was designed to create standardized communication between computers. Computers communicate by exchanging messages. The Internet supports message exchange through a mechanism called *protocols*. Protocols are very detailed and stereotyped rules explaining exactly how to exchange a particular set of messages. Each protocol is defined as a set of automata and a set of message formats. Each protocol specification defines one automaton for sending a message and another for receiving a message. The automata specify the timing of symbols that represent the messages; the automata implicitly define a grammar for the messages, indicating whether any particular message is meaningful or is interpreted by the receiver as gibberish. The protocol formats restrict the information that the protocol can express.

Security has little utility as an abstract, disembodied concept. What the word *security* should mean depends very much on the context in which it is applied. The architecture, design, and implementation of a system each determine the kind of vulnerabilities and opportunities that exist and which features are easy or hard to attack or defend.

It is fairly easy to understand why this is true. An attack on a system is an attempt to make the system act outside its specification. An attack is different from "normal" bugs that afflict computers and that occur through random interactions between the system's environment and undetected flaws in the system architecture, design, or implementation. An attack, on the other hand, is an explicit and systematic attempt by a party to search for flaws that make the computer act in a way its designers did not intend.

Computing systems consist of a large number of blocks or modules assembled together, each of which provides an intended set of functions. The system architecture hooks the modules together through *interfaces*, through which the various modules exchange information to activate the functions provided by each module in a coordinated way. These interfaces may be explicit, such as a formal grammar that the automata are supposed to conform, or they may be implicit, as when a parser accepts a larger grammar than is in the specification. An attacker exploits the architecture to compromise the computing system by interjecting inputs into these interfaces that do not conform to the intended specification of inputs into one of the automata. If the targeted module has not been carefully crafted, unexpected inputs can cause it to behave in unintended ways. This implies that the security of a system is determined by its decomposition into modules, which an adversary exploits by injecting messages into the interfaces the architecture exposes. Accordingly, no satisfying discussion of any system is feasible without an understanding of the system architecture. Our first goal, therefore, is to review the architecture of the

Internet communication protocols in an effort to gain a deeper understanding of its vulnerabilities.

Communications Architecture Basics

Since communication is an extremely complex activity, it should come as no surprise that the system components providing communication decompose into modules. One standard way to describe each communication module is as a black box with a well-defined service interface. A minimal communications service interface requires four primitives:

- *A send primitive, which an application using the communications module uses to send a message via the module to a peer application executing on another networked device*. The *send* primitive specifies a message payload and a destination, as well as a format forhow messages are encoded from this information. The communication module responding to the *send* transmits the message to the specified destination, reporting its requestor as the message source.
- *A confirm primitive, to report that the module has sent a message to the designated destination in response to a send request or to report when the message transmission failed, along with any failure details that might be known*. It is possible to combine the *send* and *confirm* primitives, but network architectures rarely take this approach at their lowest layer. The *send* primitive is normally defined to allow the application to pass a message to the communications module for transmission by transferring control of a buffer containing the message. The *confirm* primitive then releases the buffer back to the calling application when the message has indeed been sent. This scheme affects "a conservation of buffers" and enables the communications module and the application using it to operate in parallel, thus enhancing the overall communication performance.
- *A listen primitive, which the receiving application uses to provide the communications module with buffers into which it should put messages arriving from the network*. Each buffer the application posts must be large enough to receive a message of the maximum expected size. The receiving automata must be carefully designed to respond correctly to arriving messages that are too large for the receive buffer.
- *A receive primitive, to deliver a received message from another party to the receiving application*. This releases a posted buffer back to the application and usually generates a signal to notify the application of message arrival. The released buffer contains the received message and the (alleged) message source.

Sometimes the *listen* primitive is replaced with a *release* primitive. In this model, the receive buffer is owned by the receiving communications module instead of the application, and the application must recycle buffers containing received messages back to the communication module upon completion. In this case the buffer size selected by the receiving module determines the maximum message size. In a moment we will explain how network protocols work around this restriction.

It is customary to include a fifth service interface primitive for communications modules:

- A *status* primitive, to report diagnostic and performance information about the underlying communications. This might report statistics, the state of active associations with other network devices, and the like.

Communications is affected by providing a communications module black box on systems, connected by a signaling medium. The medium connecting the two devices constitutes the network communications path. The media can consist of a direct link between the devices or, more commonly, several intermediate relay systems between the two communicating endpoints. Each relay system is itself a communicating device with its own communications module, which receives and then forward messages from the initiating system to the destination system.

Under this architecture, a message is transferred from an application on one networked system to an application on a second networked system as follows:

First, the application sourcing the message invokes the *send* primitive exported by its communications module. This causes the communications module to (attempt) to transmit the message to a destination provided by the application in the *send* primitive.

The communications module encodes the message onto the network's physical medium representing a link to another system. If the communications module implements a *best-effort* message service, it generates the *confirm* primitive as soon as the message has been encoded onto the medium. If the communication module implements a *reliable* message service, the communication delays generation of the *confirm* until it receives an acknowledgment from the message destination. If it has not received an acknowledgment from the receiver after some period of time, it generates a *confirm* indicating that the message delivery failed.

The encoded message traverses the network medium and is placed into a buffer by the receiving communications module of another system attached to the medium. This communications module examines the destination. The module then examines the destination specified by the message. If the module's local system is not the destination, the module reencodes the message onto the medium representing another link; otherwise the module uses the *deliver* primitive to pass the message to the receiving application.

Getting More Specific

This stereotyped description of networked communications is overly simplified. Actually, communications are torturously more difficult in real network modules. To overcome this complexity, communications modules are themselves partitioned further into layers, each providing a different networking function. The Internet decomposes communications into five layers of communications modules:

- The PHY layer
- The MAC layer
- The network layer
- The transport layer
- The sockets layer

These layers are augmented by a handful of cross-layer coordination modules. The Internet depends on the following cross-layer modules:

- ARP
- DHCP
- DNS
- ICMP
- Routing

An application using networking is also part of the overall system design, and the way it uses the network has to be taken into consideration to understand system security.

The PHY Layer

The PHY (pronounced *fie)* layer is technically not part of the Internet architecture per se, but Ethernet jacks and cables, modems, Wi-Fi adapters, and the like represent the most visible aspect of networking, and no security treatment of the Internet can ignore the PHY layer entirely.

The PHY layer module is medium dependent, with a different design for each type of medium: Ethernet, phone lines, Wi-Fi, cellular phone, OC-768, and the like are based on different PHY layer designs. It is the job of the PHY layer to translate between digital bits as represented on a computing device and the analog signals crossing the specific physical medium used by the PHY. This translation is a physics exercise.

To send a message, the PHY layer module encodes each bit of each message from the sending device as a media-specific signal or wave form, representing the bit value 1 or 0. Once encoded, the signal propagates along the medium from the sender to the receiver. The PHY layer module at the receiver decodes the medium-specific signal back into a bit. There are often special symbols representing such things as the frame start and frame end symbols, and training symbols to synchronize the receiver with the transmitter. These special symbols provide control only and are distinct from the symbols representing bits. Wave forms different from the defined symbols are undefined and discarded by the receiver.

It is possible for the encoding step at the transmitting PHY layer module to fail, for a signal to be lost or corrupted while it crosses the medium, and for the decoding step to fail at the receiving PHY layer module. It is the responsibility of higher layers to detect and recover from these potential failures.

The MAC Layer

Like the PHY layer, the MAC (pronounced *mack*) layer is not properly a part of the Internet architecture, but no satisfactory security discussion is possible without considering it. The MAC module is the "application" that uses and controls a particular PHY layer module. A MAC layer is always designed in tandem with a specific PHY (or vice versa), so a PHY−MAC pair together is often referred to as the *data link* layer.

MAC is an acronym for *media access control*. As its name suggests, the MAC layer module determines when to send and receive *frames*, which are messages encoded in a media-specific format. The job of the MAC is to pass frames over a link between the MAC layer modules on different systems.

Although not entirely accurate, it is useful to think of a MAC module as creating *links*, each of which is a communication channel between different MAC modules. It is further useful to distinguish physical links and virtual links. A *physical link* is a direct point-to-point channel between the MAC layers in two endpoint devices. A *virtual link* can be thought of as a shared medium to which more than two devices can connect at the same time. There are no physical endpoints per se; the medium acts as though it is multiplexing links between each pair of attached devices. Some media such as modern Ethernet are implemented as physical point-to-point links but act more like virtual links in that more than a single destination is reachable via the link. This is accomplished by MAC layer switching, which is also called *bridging*. Timing requirements for coordination among communicating MAC layer modules make it difficult to build worldwide networks based on MAC layer switching, however. Mobile devices such as smart phones, laptops, and notepads also make large-scale bridging difficult, since these devices can shift their attachment points to the network, thus invalidating the data structures used by switches to effect switching. Finally, some media such as Wi-Fi (IEEE 802.11) are *shared* or *broadcast media*. In a shared medium all devices can access the channel, and the MAC design must specify an access control policy

that the MAC enforces; this behavior is what gives the MAC layer its name. Ethernet was originally a shared medium, but evolved into its present switched point-to-point structure in order to simplify medium access control. The access control function of a MAC is always a complex security concern.

A MAC frame consists of a header and a data payload. The frame header typically specifies information such as the source and destination for the link endpoints. Devices attached to the medium via their MAC + PHY modules are identified by *MAC addresses*. Each MAC module has its own MAC address assigned by its manufacturer and is supposed to be a globally unique identifier. The *destination address* in a frame allows a particular MAC module to identify frames intended for it, and the *source address* allows the receiver to identify the purported frame source. The frame header also usually includes a preamble, which is a set of special PHY timing signals used to synchronize the interpretation of the PHY layer data signals representing the frame bits.

The payload portion of a frame is the data to be transferred across the network. The maximum payload size is always fixed by the medium type. It is becoming customary for most MACs to support a maximum payload size of 1500 bytes = 12,000 bits, but this is not universal. The maximum fixed size allows the MAC to make efficient use of the underlying physical medium. Since messages can be of an arbitrary length exceeding this fixed size, a higher-layer function is needed to partition messages into segments of the appropriate length.

As we have seen, it is possible for bit errors to creep into communications as signals representing bits traverse the PHY medium. MAC layers differ a great deal in how they respond to errors. Some PHY layers, such as the Ethernet PHY, experience exceedingly low error rates, and for this reason, the MAC layers for these PHYs make no attempt to more than detect errors and discard the mangled frames. Indeed, with these MACs it is cheaper for the Internet to resend message segments at a higher layer than at the MAC layer. These are called *best-effort MACs*. Others, such as the Wi-Fi MAC, experience high error rates due to the shared nature of the channel and natural interference among radio sources; experience has shown that these MACs can deliver better performance by retransmitting damaged or lost frames. It is customary for most MAC layers to append a checksum computed over the entire frame, called *a frame check sequence* (FCS). The FCS allows the receiver to detect bit errors accumulated due to random noise and other physical phenomena during transmission and due to decoding errors. Most MACs discard frames with FCS errors. Some MAC layers also perform error correction on the received bits to remove random bit errors rather than relying on retransmissions.

The Network Layer

The purpose of the network layer module is to represent messages in a media-independent manner and to forward them between various MAC layer modules representing different links. The media-independent message format is called an *Internet Protocol*, or *IP, datagram*. The network layer implements the IP layer and is the lowest layer of the Internet architecture per se.

As well as providing media independence, the network layer provides a vital forwarding function that works even for a worldwide network like the Internet. It is impractical to form a link directly between each communicating system on the planet. Indeed, the cabling costs alone are prohibitive—no one wants billions, or even dozens, of cables connecting their computer to other computers—and too many MAC + PHY interfaces can quickly exhaust the power budget for a single computing system. Hence, each machine is attached by a small number of links to other devices, and some of the machines with multiple links comprise a *switching fabric*. The computing systems constituting the switching fabric are called *routers*.

The forwarding function supported by the network layer module is the key component of a router and works as follows: When a MAC module receives a frame, it passes the frame payload to the network layer module. The payload consists of an *IP datagram*, which is the media-independent representation of the message. The receiving network layer module examines the datagram to see whether to deliver it locally or to pass it on toward the datagram's ultimate destination. To accomplish the latter, the network layer module consults a *forwarding table* to identify some neighbor router closer to the ultimate destination than itself. The forwarding table also identifies the MAC module to use to communicate with the selected neighbor and passes the datagram to that MAC layer module. The MAC module in turn retransmits the datagram as a frame encoded for its medium across its link to the neighbor. This process happens recursively until the datagram is delivered to its ultimate destination.

The network layer forwarding function is based on *IP addresses*, a concept that is critical to understanding the Internet architecture. An IP address is a media-independent name for one of the MAC layer modules within a computing system. Each IP address is structured to represent the "location" of the MAC module within the entire Internet. This notion of location is relative to the graph comprising routers and their interconnecting links, called the *network topology*, not to actual geography. Since this name represents a location, the forwarding table within each IP module can use the IP address of the ultimate destination as a sort of signpost pointing at the MAC module with the greatest likelihood of leading to the ultimate destination of a particular datagram.

An IP address is different from the corresponding MAC address already described. A MAC address is a permanent, globally unique identifier, identifying a particular interface on a particular computing device, whereas an IP address can be dynamic due to device mobility. An IP address cannot be assigned by the equipment manufacturer, since a computing device can change locations frequently. Hence, IP addresses are administered and blocks allocated to different organizations with an Internet presence. It is common, for instance, for an Internet service provider (ISP) to acquire a large block of IP addresses for use by its customers.

An IP datagram has a structure similar to that of a frame: It consists of an IP header, which is "extra" overhead used to control the way a datagram passes through the Internet, and a data payload, which contains the message being transferred. The IP header indicates the ultimate source and destinations, represented as IP addresses.

The IP header format limits the size of an IP datagram payload to 64 K ($2^{16} = 65{,}536$) bytes. It is common to limit datagram sizes to the underlying media size, although datagrams larger than this do occur. This means that normally each MAC layer frame can carry a single IP datagram as its data payload. IP version 4 or higher, still the dominant version deployed on the Internet today, allows fragmentation of larger datagrams, to split large datagrams into chunks small enough to fit the limited frame size of the underlying MAC layer medium. IPv4 or higher reassembles any fragmented datagrams at the ultimate destination. IP version 6 or higher, which is becoming more widely deployed due to its widespread use in smart phone networks and Asia, does not support fragmentation and reassembly; this removes from IPv6 or higher one of the attack vectors enabled by IPv4 or higher.

Network layer forwarding of IP datagrams is best effort and is not reliable. Network layer modules along the path taken by any message can lose and reorder datagrams. It is common for the network layer in a router to recover from congestion—that is, when the router is overwhelmed by more receive frames than it can process—by discarding late-arriving frames until the router has caught up with its forwarding workload. The network layer can reorder datagrams when the Internet topology changes, because a new path between source and destination might be shorter or longer than an old path, so datagrams in flight before the change can arrive after frames sent following the change. The Internet architecture delegates recovery from these problems to high-layer modules.

Some applications, such as those utilizing voice and video, do not respond well to reordering because it imposes a severe performance penalty on the application. In order to better accommodate the needs of these types of message traffic, the Internet has begun to implement protocols such as MPLS, which mimics the switched circuit mechanisms of phone networks. That is, these protocols create *flows* through the Internet that suppress datagram reordering. Circuit switching uses network resources differently than best-effort forwarding, and network links in the core of the network usually require greater bandwidth for the two technologies to successfully coexist.

The Transport Layer

The transport layer is implemented by TCP and similar protocols. Not all transport protocols provide the same level of service as TCP, but a description of TCP will suffice to help us understand the issues addressed by the transport layer. The transport layer provides a multitude of functions.

First, the transport layer creates and manages instances of two-way channels between communication endpoints. These channels are called *connections*. Each connection represents a virtual endpoint between a pair of communication endpoints. A connection is named by a pair of IP addresses and *port numbers*. Two devices can support simultaneous connections using different port numbers for each connection. It is common to differentiate applications on the same host through the use of port numbers.

A second function of the transport layer is to support delivery of messages of arbitrary length. The 64 K byte limit of the underlying IP module is too small to carry really large messages, and the transport layer module at the message source chops messages into pieces called *segments* that are more easily digestible by lower-layer communications modules. The segment size is negotiated between the two transport endpoints during connection setup. The segment size is chosen by discovering the smallest maximum frame size supported by any MAC + PHY link on the path through the Internet used by the connection setup messages. Once this is known, the transmitter typically partitions a large message into segments no larger than this size, plus room for an IP header. The transport layer module passes each segment to the network layer module, where it becomes the payload for a single IP datagram. The destination network layer module extracts the payload from the IP datagram and passes it to the transport layer module, which interprets the information as a message segment. The destination transport reassembles this into the original message once all the necessary segments arrive.

Of course, as noted, MAC frames and IP datagrams can be lost in transit, so some segments can be lost. It is the responsibility of the transport layer module to detect this loss and retransmit the missing segments. This is accomplished by a sophisticated acknowledgment algorithm defined by the transport layer. The destination sends a special acknowledgment message, often piggybacked with a data segment being sent in the opposite direction, for each segment that arrives. Acknowledgments can be

lost as well, and if the message source does not receive the acknowledgment within a time window, the source retransmits the unacknowledged segment. This process is repeated a number of times, and if the failure continues, the network layer tears down the connection because it cannot fulfill its reliability commitment.

One reason for message loss is congestion at routers, something blind retransmission of unacknowledged segments will only exacerbate. The network layer is also responsible for implementing congestion control algorithms as part of its transmit function. TCP, for instance, lowers its transmit rate whenever it fails to receive an acknowledgment message in time, and it slowly increases its rate of transmission until another acknowledgment is lost. This allows TCP to adapt to congestion in the network, helping to minimize frame loss.

It can happen that segments arrive at the destination out of order, since some IP datagrams for the same connection could traverse the Internet through different paths due to dynamic changes in the underlying network topology. The transport layer is responsible for delivering the segments in the order sent, so the receiver caches any segments that arrive out of order prior to delivery. The TCP reordering algorithm is closed tied to the acknowledgment and congestion control scheme so that the receiver never has to buffer too many out-of-order received segments and the sender not too many sent but unacknowledged segments.

Segment data arriving at the receiver can be corrupted due to undetected bit errors on the data link and copy errors within routers and the sending and receiving computing systems. Accordingly, all transport layers use a checksum algorithm called a *cyclic redundancy check* (CRC) to detect such errors. The receiving transport layer module typically discards segments with errors detected by the CRC algorithm, and recovery occurs through retransmission by the sender when it fails to receive an acknowledgment from the receiver for a particular segment.

The Sockets Layer

The top layer of the Internet, the sockets layer, does not *per se* appear in the architecture at all. The sockets layer provides a set of interfaces, each of which represents a logical communications endpoint. An application can use the sockets layer to create, manage, and destroy connection instances using a socket as well as send and receive messages over the connection. The sockets layer has been designed to hide much of the complexity of the transport layer, thereby making TCP easier to use. The sockets layer has been highly optimized over the years to deliver as much performance as possible, but it does impose a performance penalty. Applications with very demanding performance requirements tend to utilize the transport layer directly instead of through the sockets layer module, but this comes with a very high cost in terms of software maintenance.

In most implementations of these communications modules, each message is copied twice, at the sender and the receiver. Most operating systems are organized into user space, which is used to run applications, and kernel space, where the operating system itself runs. The sockets layer occupies the boundary between user space and kernel space. The sockets layer's *send* function copies a message from memory controlled by the sending application into a buffer controlled by the kernel for transmission. This copy prevents the application from changing a message it has posted to send, but it also permits the application and kernel to continue their activities in parallel, thus better utilizing the device's computing resources. The sockets layer invokes the transport layer, which partitions the message buffer into segments and passes the address of each segment to the network layer. The network layer adds its headers to form datagrams from the segments and invokes the right MAC layer module to transmit each datagram to its next hop. A second copy occurs at the boundary between the network layer and the MAC layer, since the data link must be able to asynchronously match transmit requests from the network layer to available transmit slots on the medium provided by its PHY. This process is reversed at the receiver, with a copy of datagrams across the MAC-network layer boundary and of messages between the socket layer and application.

Address Resolution Protocol

The network layer uses Address Resolution Protocol, or ARP, to translate IP addresses into MAC addresses, which it needs to give to the MAC layer in order to deliver frames to the appropriate destination.

The ARP module asks the question, "Who is using IP address *X*?" The requesting ARP module uses a request/response protocol, with the MAC layer broadcasting the ARP module's requests to all the other devices on the same physical medium segment. A receiving ARP module generates a response only if its network layer has assigned the IP address to one of its MAC modules. Responses are addressed to the requester's MAC address. The requesting ARP module inserts the response received in an address translation table used by the network layer to identify the next hop for all datagrams it forwards.

Dynamic Host Configuration Protocol

Remember that unlike MAC addresses, IP addresses cannot be assigned in the factory, because they are dynamic and must reflect a device's current location within the Internet. A MAC module uses Dynamic Host

Configuration Protocol, or DHCP, to acquire an IP address for itself to reflect the device's current location with respect to the Internet topology.

DHCP makes the request: "Please configure my MAC module with an IP address." When one of a device's MAC layer modules connects to a new medium, it invokes DHCP to make this request. The associated DHCP module generates such a request that conveys the MAC address of the MAC module, which the MAC layer module broadcasts to the other devices attached to the same physical medium segment. A DHCP server responds with a unicast DHCP response binding an IP address to the MAC address. When it receives the response, the requesting DHCP module passes the assigned IP address to the network layer to configure in its address translation table.

In addition to binding an IP address to the MAC module used by DHCP, the response also contains a number of network configuration parameters, including the address of one or more routers, to enable reaching arbitrary destinations, the maximum datagram size supported, and the addresses of other servers, such as DNS servers, that translate human-readable names into IP addresses.

Domain Naming Service

IP and MAC addresses are efficient means for identifying different network interfaces, but human beings are incapable of using these as reliably as computing devices can. Instead, human beings rely on names to identify the computing devices with which they want to communication. These names are centrally managed and called *domain names*. The Domain Naming Service, or DNS, is a mechanism for translating human-readable names into IP addresses.

The translation from human-readable names to IP addresses happens within the socket layer module. An application opens a socket with the name of the intended destination. As the first step of opening a connection to that destination, the socket sends a request to a DNS server, asking the server to translate the name into an IP address. When the server responds, the socket can open the connection to the right destination, using the IP address provided.

It is becoming common for devices to register their IP addresses under their names with DNS once DHCP has completed. This permits other devices to locate the registering device so that they can send messages to it.

Internet Control Message Protocol

Internet Control Message Protocol (ICMP) is an important diagnostic tool for troubleshooting the Internet. Though ICMP provides many specialized message services, three are particularly important:

- *Ping*. Ping is a request/response protocol designed to determine the reachability of another IP address. The requestor sends a ping request message to a designated IP address. If the ping message is delivered, the interface using the destination IP address sends a ping response message to the IP address that sourced the request. The responding ICMP module copies the contents of the ping request into the ping response so that the requestor can match responses to requests. The requestor uses pings to measure the roundtrip time to a destination, among other things.
- *Traceroute*. Traceroute is another request/response protocol. An ICMP module generates a traceroute request to discover the path it is using to traverse the Internet to a destination IP address. The requesting ICMP module transmits a destination. Each router that handles the traceroute request adds a description of its own IP address that received the message and then forwards the updated traceroute request. The destination sends all this information back to the message source in a traceroute response message.
- *Destination unreachable*. When a router receives a datagram for which it has no next hop, it generates a "destination unreachable" message and sends it back to the datagram source. When the message is delivered, the ICMP module marks the forwarding table of the message source so that its network layer will reject further attempts to send messages to the destination IP address. An analogous process happens at the ultimate destination when a message is delivered to a network layer, but the application targeted to receive the message is no longer online. The purpose of "destination unreachable" messages is to suppress messages that will never be successfully delivered in order to reduce network congestion.

Routing

The last cross-layer module we'll discuss is *routing*. Routing is a middleware application to maintain the forwarding tables used by the network layer. Each router advertises itself by periodically broadcasting "hello" messages through each of its MAC interfaces. This allows routers to discover the presence or loss of all neighboring routers, letting them construct the one-hop topology of the part of the Internet directly visible through their directly attached media. The routing application in a router then uses a sophisticated gossiping mechanism to exchange this view of the local topology with their neighbors. Since some of a router's neighbors are not its own direct neighbors, this allows each router to learn the two-hop topology of the Internet. This process repeats recursively until each router knows the entire topology of the Internet. The cost of using each link is part of the information gossiped. A routing module receiving this information uses all of it to compute a lowest-cost route to each destination. Once this is accomplished, the routing

module reconfigures the forwarding table maintained by its network layer module. The routine module updates the forwarding table whenever the Internet topology changes, so each network layer can make optimal forwarding decisions in most situations and at the very worst reach any other device that is also connected to the Internet.

There are many different routing protocols, each of which is based on different gossiping mechanisms. The most widely deployed routing protocol between different administrative domains within the Internet is the border gateway protocol (BGP). The most widely deployed routing protocols within wired networks controlled by a single administrative domain are OSPF and RIP. AODV, OLSR, and TBRPF are commonly used in Wi-Fi meshes. Different routing protocols are used in different environments because each one addresses different scaling and administrative issues.

Applications

Applications are the ultimate reason for networking, and the Internet architecture has been shaped by applications' needs. All communicating applications define their own language in which to express what they need to say. Applications generally use the sockets layer to establish communication channels, which they then use for their own purposes.

Since the network modules have been designed to be a generic communications vehicle, that is, designed to meet the needs of all (or at least most) applications, it is rarely meaningful for the network to attempt to make statements on behalf of the applications. There is widespread confusion on this point around authentication and key management, which are the source of many exploitable security flaws.

2. AN INTERNET THREAT MODEL

Now that we have reviewed the architecture of the Internet protocol suite, it is possible to constructively consider the security issues it raises. Before doing so, let's first set the scope of the discussion.

There are two general approaches to attacking a networked computer. The first is to compromise one of the communicating parties so that it responds to queries with lies or otherwise communicates in a manner not foreseen by the system designers of the receiver. For example, it has become common to receive email with virus-infected attachments, whereby opening the attachment infects the receiver with the virus. These messages typically are sent by a machine that has already been compromised, so the sender is no longer acting as intended by the manufacturer of the computing system. Problems of this type are called *Byzantine failures*, named after the Byzantine Generals problem.

The Byzantine Generals problem imagines several armies surrounding Byzantium. The generals commanding these armies can communicate only by exchanging messages transported by couriers between them. Of course the couriers can be captured and the messages replaced by forgeries, but this is not really the issue, since it is possible to devise message schemes that detect lost messages or forgeries. All the armies combined are sufficient to overwhelm the defenses of Byzantium, but if even one army fails to participate in a coordinated attack, the armies of Byzantium have sufficient strength to repulse the attack. Each general must make a decision as to whether to participate in an attack on Byzantium at dawn or withdraw to fight another day. The question is how to determine the veracity of the messages received on which the decision to attack will be made—that is, whether it is possible to detect that one or more generals have become traitors and so will say their armies will join the attack when in fact they plan to hold back so that their allies will be slaughtered by the Byzantines.

Practical solutions addressing Byzantine failures fall largely within the purview of platform rather than network architecture, although the interconnectivity topology is an important consideration. For example, since viruses infect a platform by buffer overrun attacks, platform mechanisms to render buffer overrun attacks futile are needed. Secure logging, to make an accurate record of messages exchanged, is a second deterrent to these sorts of attacks; the way to accomplish secure logging is usually a question of platform design. Most self-propagating viruses and worms utilize the Internet to propagate, but they do not utilize any feature of the Internet architecture per se for their success. The success of these attacks instead depends on the architecture, design, implementation, and policies of the receiving system. Although these sorts of problems are important, we will rarely focus on security issues stemming from Byzantine failures.

What will instead be the focus of the discussion are attacks on the messages exchanged between computers themselves. As we will see, even with this more limited scope, there are plenty of opportunities for things to go wrong.

The Dolev–Yao Adversary Model

Security analyses of systems traditionally begin with a model of the attacker, and we follow this tradition. Daniel Dolev and Andrew Chi-Chih Yao formulated the standard attack model against messages exchanged over a network. The *Dolev-Yao model* makes the following assumptions about an attacker:

- *Eavesdrop*. An adversary can listen to any message exchanged through the network.

- *Forge*. An adversary can create and inject entirely new messages into the datastream or change messages in flight; these messages are called *forgeries*.
- *Replay*. A special type of forgery, called a *replay*, is distinguished. To replay a message, the adversary resends legitimate messages that were sent earlier.
- *Delay and rush*. An adversary can delay the delivery of some messages or accelerate the delivery of others.
- *Reorder*. An adversary can alter the order in which messages are delivered.
- *Delete*. An adversary can destroy in-transit messages, either selectively or all the messages in a datastream.

This model assumes a very powerful adversary, and many people who do not design network security solutions sometimes assert that the model grants adversaries an unrealistic amount of power to disrupt network communications. However, experience demonstrates that it is a reasonably realistic set of assumptions in practice; examples of each threat abound, as we will see. One of the reasons for this is that the environment in which the network operates is exposed and therefore open to attack by a suitably motivated adversary; unlike memory or microprocessors or other devices internal to a computer, there is almost no assurance that the network medium will be deployed in a "safe" way (Indeed, malware has progressed to the point where internal buses and memories can no longer be considered secure against knowledgeable attackers, which is forcing a migration of network security techniques into the platforms themselves). That is, it is comparatively easy for an attacker to anonymously access the physical network fabric, or at least the medium monitored to identify attacks against the medium and the networked traffic it carries. And since a network is intended as a generic communications vehicle, it becomes necessary to adopt a threat model that addresses the needs of all possible applications.

Layer Threats

With the Dolev−Yao model in hand, we can examine each of the architectural components of the Internet protocol suite for vulnerabilities. We next look at threats each component of the Internet architecture exposes through the prism of this model. The first Dolev−Yao assumption about adversaries is that they can eavesdrop on any communications.

Eavesdropping

An attacker can eavesdrop on a communications medium by connecting a receiver to the medium. Ultimately, such a connection has to be implemented at the PHY layer because an adversary has to access some physical media somewhere to be able to listen to anything at all. This connection to the PHY medium might be legitimate, such as when an authorized device is uncompromised, or illegitimate, such as an illegal wiretap; it can be intentional, as when an eavesdropper installs a rogue device, or unintentional, such as a laptop with wireless capabilities that will by default attempt to connect to any Wi-Fi network within range.

With a PHY layer connection, the eavesdropper can receive the analog signals on the medium and decode them into bits. Because of the limited scope of the PHY layer function—there are no messages, only analog signals representing bits and special control symbols—the damage an adversary can do with only PHY layer functionality is rather limited. In particular, to make sense of the bits, an adversary has to impose the higher-layer frame and datagram formats onto the received bits. That is, any eavesdropping attack has to take into account at least the MAC layer to learn anything meaningful about the communications. Real eavesdroppers are more sophisticated than this: They know how to interpret the bits as a medium-specific encoding with regard to the frames that are used by the MAC layer. They also know how to extract the media-independent representation of datagrams conveyed within the MAC frames, as well as how to extract the transport layer segments from the datagrams, which can be reassembled into application messages.

The defenses erected against any threat give some insight into the perceived danger of the threat. People are generally concerned about eavesdropping, and it is easy to illicitly attach listening devices to most PHY media, but detection and removal of wiretaps has not evolved into a comparatively large industry. An apparent explanation of why this is so is that it is easier and more cost effective for an attacker to compromise a legitimate device on the network and configure it to eavesdrop than it is to install an illegitimate device. The evidence for this view is that the antivirus/antibot industry is gigantic by comparison.

There is another reason that an antiwiretapping industry has never developed for the Internet. Almost every MAC module supports a special mode of operation called *promiscuous mode*. A MAC module in promiscuous mode receives every frame appearing on the medium, not just the frames addressed to itself. This allows one MAC module to snoop on frames that are intended for other parties. Promiscuous mode was intended as a troubleshooting mechanism to aid network administrators in diagnosing the source of problems. However, it is also a mechanism that can be easily abused by anyone motivated to enable promiscuous mode on their own networking devices.

Forgeries

A second Dolev−Yao assumption is that the adversary can forge messages. Eavesdropping is usually fairly

innocuous compared to forgeries, because eavesdropping merely leaks information, whereas forgeries cause an unsuspecting receiver to take actions based on false information. Hence, the prevention or detection of forgeries is one of the central goals of network security mechanisms. Different kinds of forgeries are possible for each architectural component of the Internet. We will consider only a few for each layer of the Internet protocol suite, to give a taste of their variety and ingenuity.

Unlike the eavesdropping threat, where knowledge of higher layers is essential to any successful compromise, an attacker with only a PHY layer transmitter (and no higher-layer mechanisms) can disrupt communications by *jamming* the medium—that is, outputting noise onto the medium in an effort to disrupt communications. A jammer creates signals that do not necessarily correspond to any wave forms corresponding to bit or other control symbols. The goal of a pure PHY layer jammer is denial of service (DoS)—that is, to fill the medium sufficiently so that no communications can take place.

Sometimes it is feasible to create a jamming device that is sensitive to the MAC layer formats above it, to selectively jam only some frames. Selective jamming requires a means to interpret bits received from the medium as a higher-layer frame or datagram, and the targeted frames to jam are recognized by some criterion, such as being sent from or to a particular address. So that it can enable its own transmitter before the frame has been entirely received by its intended destination, the jammer's receiver must recognize the targeted frames before they are fully transmitted. When this is done correctly, the jammer's transmitter interferes with the legitimate signals, thereby introducing bit errors in the legitimate receiver's decoder. This results in the legitimate receiver's MAC layer detecting the bit errors while trying to verify the frame check sequence, causing it to discard the frame. Selective jamming is harder to implement than continuous jamming, but it is also much harder to detect, because the jammer's signal source transmits only when legitimate devices transmit as well, and only the targeted frames are disrupted. Successful selective jamming usually causes administrators to look for the source of the communications failure on one of the communicating devices instead of in the network for a jammer.

There is also a higher-layer analog to jamming, called *message flooding*. Denial of service (DoS) is also the goal of message flooding. The technique used by message flooding is to create and send messages at a rate high enough to exhaust some resource. It is popular today, for instance, for hackers to compromise thousands of unprotected machines, which they use to generate simultaneous messages to a targeted site. Examples of this kind of attack are to completely fill the physical medium connecting the targeted site to the Internet with network layer datagrams—this is usually hard or impossible—or to generate transport layer connection requests at a rate faster than the targeted site can respond. Other variants—request operations that lead to disk I/O or require expensive cryptographic operations—are also common. Message flooding attacks have the property that they are legitimate messages from authorized parties but simply timed so that collectively their processing exceeds the maximum capacity of the targeted system.

Let's turn away from resource-clogging forgeries and examine forgeries designed to cause a receiver to take an unintended action. It is possible to construct this type of forgery at any higher layer: forged frames, datagrams, network segments, or application messages.

To better understand how forgeries work, we need to examine Internet "identities" more closely—MAC addresses, IP addresses, transport port numbers, and DNS names—as well as the modules that use or support their use. The threats are a bit different at each layer.

Recall that each MAC layer module is manufactured with its own "hardware" address, which is supposed to be a globally unique identifier for the MAC layer module instance. The hardware address is configured in the factory into nonvolatile memory. At boot time, the MAC address is transferred from nonvolatile memory into operational RAM maintained by the MAC module. A transmitting MAC layer module inserts the MAC address from RAM into each frame it sends, thereby advertising an "identity." The transmitter also inserts the MAC address of the intended receiver on each frame, and the receiving MAC layer matches the MAC address in its own RAM against the destination field in each frame sent over the medium. The receiver ignores the frame if the MAC addresses don't match and receives the frame otherwise.

In spite of this system, it is useful—even necessary sometimes—for a MAC module to change its MAC address. For example, sometimes a manufacturer accidentally recycles MAC addresses so that two different modules receive the same MAC address in the factory. If both devices are deployed on the same network, neither works correctly until one of the two changes its address. Because of this problem, all manufacturers provide a way for the MAC module to alter the address in RAM. This can always be specified by software via the MAC module's device driver, by replacing the address retrieved from hardware at boot time.

Since the MAC address can be changed, attacks will find it. A common attack in Wi-Fi networks, for instance, is for the adversary to put the MAC module of the attacking device into promiscuous mode, to receive frames from other nearby systems. It is usually easy to identify another client device from the received frames and extract

its MAC address. The attacker then reprograms its own MAC module to transmit frames using the address of its victim. A goal of this attack is usually to "hijack" the session of a customer paying for Wi-Fi service; that is, the attacker wants free Internet access for which someone else has already paid. Another goal of such an attack is often to avoid attribution of the actions being taken by the attacker; any punishment for antisocial or criminal behavior will likely be attributed to the victim instead of the attacker because all the frames that were part of the behavior came from the victim's address.

A similar attack is common at the network layer. The adversary will snoop on the IP addresses appearing in the datagrams encoded in the frames and use these instead of their own IP addresses to source IP datagrams. This is a more powerful attack than that of utilizing only a MAC address, because IP addresses are global; an IP address is an Internet-wide locator, whereas a MAC address is only an identifier on the medium to which the device is physically connected.

Manipulation of MAC and IP addresses leads directly to a veritable menagerie of forgery attacks and enables still others. A very selective list of examples must suffice to illustrate the ingenuity of attackers:

- TCP uses sequence numbers as part of its reliability scheme. TCP is supposed to choose the first sequence number for a connection randomly. If an attacker can predict the first sequence number for a TCP connection, an attacker who spoofs the IP address of one of the parties to the connection can hijack the session by interjecting its own datagrams into the flow that use the correct sequence numbers. This desynchronizes the retry scheme for the device being spoofed, which then drops out from the conversation. This attack seems to have become relatively less common than other attacks over the past few years, since most TCP implementations have begun to utilize better random number generators to seed their sequence numbers.
- An attacker can generate an ARP response to any ARP request, thus claiming to use any requested IP address. This is a common method to hijack another machine's IP address; it is a very effective technique when the attacker has a fast machine and the victim machine has less processing power, and so responds more slowly.
- An attacker can generate DHCP response messages replying to DHCP requests. This technique is often used as part of a larger forgery, such as the evil twin attack, whereby an adversary masquerades as an access point for a Wi-Fi public hot spot. The receipt of DHCP response messages convinces the victim it is connecting to an access point operated by the legitimate hotspot.
- A variant is to generate a DHCP request with the hardware MAC address of another device. This method is useful when the attacker wants to ascribe action it takes over the Internet to another device.
- An attacker can impersonate the DNS server, responding to requests to resolve human-readable names into IP addresses. The IP address in the response messages points the victim to a site controlled by the attacker. This is becoming a common attack used by criminals attempting to commit financial fraud, such as stealing credit card numbers.

Replay

Replay is a special forgery attack. It occurs when an attacker records frames or datagrams and then retransmits them unchanged at a later time.

This might seem like an odd thing to do, but replay attacks are an especially useful way to attack stateful messaging protocols, such as a routing protocol. Since the goal of a routing protocol is to allow every router to know the current topology of the network, a replayed routing message can cause the routers receiving it to utilize out-of-date information.

An attacker might also respond to an ARP request sent to a sabotaged node or to a mobile device that has migrated to another part of the Internet by sending a replayed ARP response. This replay indicates the node is still present, thus masking the true network topology.

Replay is also often a valuable tool for attacking a message encryption scheme. By retransmitting a message, an attacker can sometimes learn valuable information from a message decrypted and then retransmitted without encryption on another link.

A primary use of replay, however, is to attack session start-up protocols. Protocol start-up procedures establish session state, which is used to operate the link or connection and determine when some classes of failures occur. Since this state is not yet established when the session begins, start-up messages replayed from prior instances of the protocol will fool the receiver into allocating a new session. This is a common DoS technique.

Delay and Rushing

Delay is a natural consequence of implementations of the Internet architecture. Datagrams from a single connection typically transit a path across the Internet in bursts. This happens because applications at the sender, when sending large messages, tend to send messages larger than a single datagram. The transport layer partitions these messages into segments to fit the maximum segment size along the path to the destination. The MAC tends to output all the frames together as a single blast after it has accessed the

medium. Therefore, routers with many links can receive multiple datagram bursts at the same time. When this happens, a router has to temporarily buffer the burst, since it can output only one frame conveying a datagram per link at a time. Simultaneous arrival of bursts of datagrams is one source of congestion in routers. This condition usually manifests itself at the application by slow communications time over the Internet. Delay can also be intentionally introduced by routers, such as via traffic shaping.

Attackers can induce delays in several ways. We illustrate this idea by describing two different attacks. It is not uncommon for an attacker to take over a router, and when this happens, the attacker can introduce artificial delay, even when the router is uncongested. As a second example, attackers with bot armies can bombard a particular router with "filler" messages, the only purpose of which is to congest the targeted router.

Rushing is the opposite problem: a technique to make it appear that messages can be delivered sooner than can be reasonably expected. Attackers often employ rushing attacks by first hijacking routers that service parts of the Internet that are fairly far apart in terms of network topology. The attackers cause the compromised routers to form a *virtual link* between them. A virtual link emulates a MAC layer protocol but running over a transport layer connection between the two routers instead of a PHY layer. The virtual link, also called a *wormhole*, allows the routers to claim they are connected directly by a link and so are only one hop apart. The two compromised routers can therefore advertise the wormhole as a "low-cost" path between their respective regions of the Internet. The two regions then naturally exchange traffic through the compromised routers and the wormhole.

An adversary usually launches a rushing attack as a prelude to other attacks. By attracting traffic to the wormhole endpoints, the compromised routers can eavesdrop and modify the datagrams flowing through them. Compromised routers at the end of a wormhole are also an ideal vehicle for selective deletion of messages.

Reorder

A second natural event in the Internet is datagram *reordering*. The two most common reordering mechanisms are forwarding table updates and traffic-shaping algorithms. Reordering due to forwarding takes place at the network layer; traffic shaping can be applied at the MAC layer or higher.

The Internet reconfigures itself automatically as routers set up new links with neighboring routers and tear down links between routers. These changes cause the routing application on each affected router to send an update to its neighbors, describing the topology change. These changes are gossiped across the network until every router is aware of what happened. Each router receiving such an update modifies its forwarding table to reflect the new Internet topology.

Since the forwarding table updates take place asynchronously from datagram exchanges, a router can select a different forwarding path for each datagram between even the same two devices. This means that two datagrams sent in order at the message source can arrive in a different order at the destination, since a router can update its forwarding table between the selection of a next hop for different datagrams.

The second reordering mechanism is traffic shaping, which gets imposed on the message flow to make better use of the communication resources. One example is quality of service. Some traffic classes, such as voice or streaming video, might be given higher priority by routers than best-effort traffic, which constitutes file transfers. Higher priority means the router will send datagrams carrying voice or video first while buffering the traffic longer. Endpoint systems also apply traffic-shaping algorithms in an attempt to make real-time applications work better, without gravely affecting the performance of applications that can wait for their data. Any layer of the protocol stack can apply traffic shaping to the messages it generates or receives.

An attacker can emulate reordering any messages it intercepts, but since every device in the Internet must recover from message reordering anyway, reordering attacks are generally useful only in very specific contexts. We will not discuss them further.

Message Deletion

Like reordering, *message deletion* can happen through normal operation of the Internet modules. A MAC layer will drop any frame it receives with an invalid frame check sequence. A network layer module will discard any datagram it receives with an IP header error. A transport layer will drop any data segment received with a data checksum error. A router will drop perfectly good datagrams after receiving too many simultaneous bursts of traffic that lead to congestion and exhaustion of its buffers. For these reasons, TCP was designed to retransmit data segments in an effort to overcome errors.

The last class of attack possible with a Dolev–Yao adversary is message deletion. Two message deletion attacks occur frequently enough to be named: *black-hole attacks* and *gray-hole attacks*.

Black-hole attacks occur when a router deletes all messages it is supposed to forward. From time to time, a router is misconfigured to offer a zero-cost route to every destination in the Internet. This causes all traffic to be

sent to this router. Since no device can sustain such a load, the router fails. The neighboring routers cannot detect the failure rapidly enough to configure alternate routes, and they fail as well. This continues until a significant portion of the routers in the Internet fail, resulting in a black hole: Messages flow into the collapsed portion of the Internet and never flow out. A black-hole attack intentionally misconfigures a router. Black-hole attacks also occur frequently in small-scale sensor, mesh, and peer-to-peer file networks.

A gray-hole attack is a selective deletion attack. Targeted jamming is one type of selective message deletion attack. More generally, an adversary can discard any message it intercepts in the Internet, thereby preventing its ultimate delivery. An adversary intercepting and selectively deleting messages can be difficult to detect and diagnose, and so is a powerful attack. It is normally accomplished via compromised routers.

A subtler, indirect form of message deletion is also possible through the introduction of *forwarding loops*. Each IP datagram header has a *time-to-live* (TTL) field, limiting the number of hops that a datagram can make. This field is set to 255 by the initiator and decremented by each router through which the datagram passes. If a router decrements the TTL field to zero, it discards the datagram.

The reason for the TTL field is that the routing protocols that update the forwarding tables can temporarily cause forwarding loops because updates are applied asynchronously as the routing updates are gossiped through the Internet. For instance, if router A gets updated prior to router B, A might believe that the best path to some destination C is via B, whereas B believes the best route to C is via A as the next hop. Messages for C will ping-pong between A and B until one or both are updated with new topology information.

An attacker who compromises a router or forges its routing traffic can intentionally introduce forwarding routes. This causes messages addressed to the destinations affected by the forgery to circulate until the TTL field gets decremented to zero. These attacks are also difficult to detect, because all the routers are behaving according to their specifications, but messages are being mysteriously lost.

Summary

The most striking point to observe about all of the enumerated attacks is that all take advantage of the natural features and structure of the Internet architecture: No one is making any of the protocols misbehave, just “misusing” the Internet’s own features against “legitimate” use. Any I/O channel of any system—and communications over the Internet certainly falls into this bucket—is assumed under the control of an adversary under the Dolev−Yao model. The input parse for any such channel is therefore a programming environment to which we freely grant the adversary access via the language describing protocol messages on the channel. This means our communications architectures necessarily expose our systems to attack, unless we close all possible communications channels. Doing so is impractical because not all people and organizations with which they are affiliated necessarily trust one another for all possible communications, and openness is a necessary condition for our economic models. Vulnerability to attack is therefore a necessary consequence of communications and a judicious mix of security mechanisms with friends and open links with potential business partners is inevitable. Absolutely secure networks and systems have only limited utility.

3. DEFENDING AGAINST ATTACKS ON THE INTERNET

Now that we have a model for thinking about the threats against communication and we understand how the Internet works, we can examine how its communications can sometimes be protected. Here we will explain how cryptography is used to protect messages exchanged between various devices on the Internet and illustrate the techniques with examples.

As might be expected, the techniques vary according to scenario. Methods that are effective for an active session do not work for session establishment. Methods that are required for session establishment are too expensive for an established session. It is interesting that similar methods are used at each layer of the Internet architecture for protecting a session and for session establishment and that each layer defines its own security protocols. Many find the similarity of security solutions at different layers curious and wonder why security is not centralized in a single layer. We will explain why the same mechanisms solve different problems at different layers of the architecture, to give better insight into what each is for.

Layer Session Defenses

A *session* is a series of one or more related messages. The easiest and most straightforward defenses protect the exchange of messages that are organized into sessions, so we will start with session-oriented defenses.

Cryptography, when used properly, can provide reliable defenses against eavesdropping. It can also be used to detect forgery and replay attacks, and the methods used also have some relevance to detecting reordering and message deletion attacks. We will discuss how this is

accomplished and illustrate the techniques with TLS, IPsec, and 802.11i.

Defending against Eavesdropping

The primary method used to defend against eavesdropping is encryption. Encryption was invented with the goal of making it infeasible for any computationally limited adversary to be able to learn anything useful about a message that cannot already be deduced by some other means, such as its length. Encryption schemes that appear to meet this goal have been invented and are in widespread use on the Internet. Here we will describe how they are used.

There are two forms of encryption: symmetric encryption, in which the same key is used to both encrypt and decrypt, and asymmetric encryption, in which encryption and decryption use distinct but related keys. The properties of each are different. Asymmetric encryption tends to be used only for applications related to session initiation and assertions about policy (although this is not universally true). The reason for this is that a single asymmetric key operation is generally too expensive across a number of dimensions—computation time, size of encrypted payloads, power consumption—to be applied to a message stream of arbitrary length. We therefore focus on symmetric encryption and how it is used by network security protocols.

A symmetric encryption scheme consists of three operations: *key generate*, *encrypt*, and *decrypt*. The key generate operation creates a *key*, which is a secret. The key generate procedure is usually application specific; we describe some examples of key generate operations in our discussion of session start-up. Once generated, the key is used by the encrypt operation to transform *plaintext* messages—that is, messages that can be read by anyone—into *ciphertext*, which is messages that cannot be read by any computationally limited party who does not possess the key. The key is also used by the decrypt primitive to translate ciphertext messages back into plaintext messages.

There are two kinds of symmetric encryption algorithms. The first type is called a *block cipher*, and the second a *stream cipher*. Block and stream ciphers make different assumptions about the environment in which they operate, making each more effective than the other at different protocol layers.

A block cipher divides a message into chunks of a fixed size called *blocks* and encrypts each block separately. Block ciphers have the random access property, meaning that a block cipher can efficiently encrypt or decrypt any block utilizing an *initialization vector* in conjunction with the key. This property makes block ciphers a good choice for encrypting the content of MAC layer frames and network layer datagrams, for two reasons. First, the chunking behavior of a block cipher corresponds nicely to the packetization process used to form datagrams from segments and frames from datagrams. Second, and perhaps more important, the Internet architecture models the lower layers as "best-effort" services, meaning that it assumes that datagrams and frames are sent and then forgotten. If a transmitted datagram is lost due to congestion or bit error (or attack), it is up to the transport layer or application to recover. The random access property makes it easy to restart a block cipher anywhere it's needed in the datastream. Popular examples of block ciphers include AES, DES, and 3DES, used by Internet security protocols.

Block ciphers are used by the MAC and network layers to encrypt as follows: First, a block cipher mode of operation is selected. A block cipher itself encrypts and decrypts only single blocks. A mode of operation is a set of rules extending the encryption scheme from a single block to messages of arbitrary length. The most popular modes of operation used in the Internet are counter (CTR) mode and cipher-block chaining (CBC) mode. Both require an initialization vector, which is a counter value for counter mode and a randomly generated bit vector for the cipher-block chaining mode. To encrypt a message, the mode of operation first partitions the message into a sequence of blocks whose size equals that of the cipher, padding if needed to bring the message length up to a multiple of the block size. The mode of operation then encrypts each block under the key while combining initialization vectors with the block in a mode-specific fashion.

For example, counter mode uses a counter as its initialization vector, which it increments, encrypts, and then exclusive-ORs the result with the block:

$$\text{counter} \rightarrow \text{counter} + 1;\quad E \leftarrow \text{Encrypt}_{\text{Key}}(\text{counter});$$
$$\text{CipherTextBlock} \leftarrow E \oplus \text{PlainTextBlock}$$

where $\oplus$ denotes exclusive OR. The algorithm outputs the new (unencrypted) counter value, which is used to encrypt the next block and CipherTextBlock.

The process of assembling a message from a message encrypted under a mode of operation is very simple: Prepend the original initialization vector to the sequence of ciphertext blocks, which together replace the plaintext payload for the message. The right way to think of this is that the initialization vector becomes a new message header layer. Also prepended is a *key identifier*, which indicates to the receiver which key it should utilize to decrypt the payload. This is important because in many cases it is useful to employ multiple connections between the same pair of endpoints, and so the receiver can have multiple decryption keys to choose from for each message received from a particular source.

A receiver reverses this process: First, it extracts the initialization vector from the data payload, then it uses this and the ciphertext blocks to recover the original plaintext message by reversing the steps in the mode of operation.

This paradigm is widely used in MAC and network layer security protocols, including 802.11i, 802.16e, 802.1ae, and IPsec, each of which utilizes AES in modes related to counter and cipher-block chaining modes.

A stream cipher treats the data as a continuous stream and can be thought of as encrypting and decrypting data one bit at a time. Stream ciphers are usually designed so that each encrypted bit depends on all previously encrypted ones, so decryption becomes possible only if all the bits arrive in order; most true stream ciphers lack the random access property. This means that in principle stream ciphers only work in network protocols when they're used on top of a reliable data delivery service such as TCP. Therefore, they work correctly below the transport layer only when used in conjunction with reliable data links. Stream ciphers are attractive from an implementation perspective because they can often achieve much higher throughputs than block ciphers. RC4 is an example of a popular stream cipher.

Stream ciphers typically do not use a mode of operation or an initialization vector at all, or at least not in the same sense as a block cipher. Instead, they are built as pseudorandom number generators, the output of which is based on a key. The random number generator is used to create a sequence of bits that appear random, called a *key stream*, and the result is exclusive OR'd with the plaintext data to create ciphertext. Since XOR is an idempotent operation, decryption with a stream cipher is just the same operation: Generate the same key stream and exclusive OR it with the ciphertext to recover the plaintext. Since stream ciphers do not utilize initialization vectors, Internet protocols employing stream ciphers do not need the extra overhead of a header to convey the initialization vector needed by the decryptor in the block cipher case. Instead, these protocols rely on the ability of the sender and receiver to keep their respective key stream generators synchronized for each bit transferred. This implies that stream ciphers can only be used over a reliable medium such as TCP—that is, a transport that guarantees delivery of all bits in the proper order and without duplication.

Transport layer security (TLS) is an example of an Internet security protocol that uses the stream cipher RC4. TLS runs on top of TCP, which is a reliable transport and therefore meets one of the preconditions for use of RC4.

Assuming that a symmetric encryption scheme is well designed, its efficacy against eavesdropping depends on four factors. Failing to consider *any* of these factors can cause the encryption scheme to fail catastrophically.

Independence of Keys

This is perhaps the most important consideration for the use of encryption. All symmetric encryption schemes assume that the encryption key for each and every session is generated independently of the encryption keys used for every other session. Let's parse this thought:

- *Independent* means selected or generated by a process that is indistinguishable by *any* polynomial time statistical test from the uniform distribution applied to the key space. One common failure is to utilize a key generation algorithm that is not random, such as using the MAC or IP address of a device or time of session creation as the basis for a key, or even basing the key on a password. Schemes that use such public values instead of randomness for keys are easily broken using brute-force search techniques such as dictionary attacks. A second common failure is to pick an initial key randomly but create successive keys by some simple transformation, such as incrementing the initial key, exclusive OR 'ing the MAC address of the device with the key, and so on. Encryption using key generation schemes of this sort are easily broken using differential cryptanalysis and related key attacks.
- *Each and every* mean each and every. For a block cipher, reusing the same key twice with the same initialization vector can allow an adversary to recover information about the plaintext data from the ciphertext *without* using the key. Similarly, each key always causes the pseudorandom number generator at the heart of a stream cipher to generate the same key stream, and reuse of the same key stream again will leak the plaintext data from the ciphertext without using the key.
- Methods effective for the coordinated generation of random keys at the beginning of each session constitute a complicated topic. We address it in our discussion of session start-up later in the chapter.

Limited Output

Perhaps the second most important consideration is to limit the amount of information encrypted under a single key. The modern definition of security for an encryption scheme revolves around the idea of indistinguishability of the scheme's output from random. This goes back to a notion of ideal security proposed by Claude E. Shannon (a research mathematician working for Bell Labs). This has a dramatic effect on how long an encryption key may be safely used before an adversary has sufficient information to begin to learn something about the encrypted data.

Every encryption scheme is ultimately a deterministic algorithm using a finite state space, and no deterministic algorithm using a finite state space can generate an infinite amount of output that is indistinguishable from

random. This means that encryption keys must be replaced on a regular basis. The amount of data that can be safely encrypted under a single key depends very much on the encryption scheme. As usual, the limitations for block ciphers and stream ciphers are a bit different.

Let the block size for a block cipher be some integer $n > 0$. Then, for any key K, for every string S_1 there is another string S_2 so that:

$$\text{Encrypt}_K(S_2) = S_1 \text{ and } \text{Decrypt}_K(S_1) = S_2$$

This says that a block cipher's encrypt and decrypt operations are *permutations* of the set of all bit strings whose length equals the block size. In particular, this property says that every pair of distinct n bit strings results in distinct n bit ciphertexts for any block cipher. However, by an elementary theorem from probability called the birthday paradox, random selection of n bit strings should result in a 50 percent probability that some string is chosen at least twice after about $2^{n/2}$ selections. This has a sobering consequence for block ciphers. It says that an algorithm as simple as naïve guessing can distinguish the output of the block cipher from random after about $2^{n/2}$ blocks have been encrypted. This means that an encryption key should never be used to encrypt even close to $2^{n/2}$ blocks before a new, independent key is generated.

To make this specific, DES and 3DES have a block size of 64 bits; AES has a 128-bit block size. Therefore a DES or 3DES key should be used much less than to encrypt $2^{64/2} = 2^{32}$ blocks, whereas an AES key should never be used to encrypt as many as 2^{64} blocks; doing so begins to leak information about the encrypted data without use of the encryption key. As an example, 802.11i has been crafted to limit each key to encrypting 2^{48} before forcing generation of a new key.

This kind of arithmetic does not work for a stream cipher, since its block size is 1 bit. Instead, the length of time a key can be safely used is governed by the periodicity of the pseudorandom number generator at the heart of the stream cipher. RC4, for instance, becomes distinguishable from random after generating about 2^{31} bytes. Note that $31 \approx 32 = \sqrt{256}$, and 256 bytes is the size of the RC4 internal state. This illustrates the rule of thumb that there is a birthday paradox relation between the maximum number of encrypted bits of a stream cipher key and its internal state.

Key Size

The one "fact" about encryption that everyone knows is that larger keys result in stronger encryption. This is indeed true, provided that the generate keys operation is designed according to the independence condition. One common mistake is to properly generate a short key—say, 32 bits long—that is then concatenated to get a key of the length needed by the selected encryption scheme—say, 128 bits. Another similar error is to generate a short key and manufacture the remainder of the key with known public data, such as an IP address. These methods result in a key that is only as strong as the short key that was generated randomly.

Mode of Operation

The final parameter is the mode of operation—that is, the rules for using a block cipher to encrypt messages whose length is different from the block cipher width. The most common problem is failure to respect the documented terms and conditions defined for using the mode of operation.

As an illustration of what can go wrong—even by people who know what they are doing—the cipher-block chaining mode requires that the initialization vector be chosen randomly. The earliest version of the IPsec standard used the cipher-block chaining mode exclusively for encryption. This standard recommended choosing initialization vectors as the final block of any prior message sent. The reasoning behind this recommendation was that, because an encrypted block cannot be distinguished from random if the number of blocks encrypted is limited, a block of a previously encrypted message ought to suffice. However, the advice given by the standard was erroneous because the initialization vector selection algorithm failed to have one property that a real random selection property has: The initialization vector is not unpredictable. A better way to meet the randomness requirement is to increment a counter, prepend it to the message to encrypt, and then encrypt the counter value, which becomes the initialization vector. This preserves the unpredictability property at a cost of encrypting one extra block.

A second common mistake is to design protocols using a mode of operation that was not designed to encrypt multiple blocks. For example, failing to use a mode of operation at all—using the naked encrypt and decrypt operations, with no initialization vector—is itself a mode of operation called *electronic code book* mode. Electronic code book mode was designed to encrypt messages that never span more than a single block—for example, encrypting keys to distribute for other operations. Using electronic code book mode on a message longer than a single block leaks a bit per block, however, because this mode allows an attacker to disguise when two plaintext blocks are the same or different. A classical example of this problem is to encrypt a photograph using electronic code book mode. The main outline of the photograph shows through plainly. This is not a failure of the encryption scheme; it is, rather, using encryption in a way that was never intended.

Now that we understand how encryption works and how it is used in Internet protocols, we should ask why it is needed at different layers. What does encryption at each layer of the Internet architecture accomplish? The best way to answer this question is to watch what it does.

Encryption applied at the MAC layer encrypts a single link. Data is encrypted prior to being put on a link and is decrypted again at the other end of a link. This leaves the IP datagrams conveyed by the MAC layer frames exposed inside each router as they wend their way across the Internet. Encryption at the MAC layer is a good way to transparently prevent data from leaking, since many devices never use encryption. For example, many organizations are distributed geographically and use direct point-to-point links to connect sites; encrypting the links connecting sites prevents an outsider from learning the organization's confidential information merely by eavesdropping. Legal wiretaps also depend on this arrangement because they monitor data inside routers. The case of legal wiretaps also illustrates the problem with link layer encryption only: If an unauthorized party assumes control of a router, he or she is free to read all the datagrams that traverse the router.

IPsec operates essentially at the network layer. Applying encryption via IPsec prevents exposure of the datagrams' payload end to end, so the data is still protected within routers. Since the payload of a datagram includes both the transport layer header and its data segments, applying encryption at the IPsec layer hides the applications being used as well as the data. This provides a big boost in confidentiality but also leads to more inefficient use of the Internet, since traffic-shaping algorithms in routers critically depend on having complete access to the transport headers. Using encryption at the IPsec layer also means the endpoints do not have to know whether each link a datagram traverses through the Internet applies encryption; using encryption at this layer simplifies the security analysis over encryption applied at the MAC layer alone. Finally, like MAC layer encryption, IPsec is a convenient tool for introducing encryption transparently to protect legacy applications, which by and large ignored confidentiality issues. A downside of IPsec is that it still leaves data unprotected within the network protocol implementation, and malware can sometimes hook itself between the network and sockets layer to inspect traffic.

The transport layer encryption function can be illustrated by TLS. Like IPsec, TLS operates end to end, but TLS encrypts only the application data carried in the transport data segments, leaving the transport header exposed. Thus, with TLS, routers can still perform their traffic-shaping function, and we still have the simplified security analysis that comes with end-to-end encryption. A second advantage is that TLS protects data essentially from application to application, making malware attacks against the communication channel per se more difficult. There are of course downsides. The first disadvantage of this method is that the exposure of the transport headers gives the attacker greater knowledge about what might be encrypted in the payload. The second disadvantage is that it is somewhat more awkward to introduce encryption transparently at the transport layer; encryption at the transport layer requires cooperation by the application to perform properly. This analysis says that it is reasonable to employ encryption at any one of the network protocol layers because each solves a slightly different problem.

Before leaving the topic of encryption, it is worthwhile to emphasize what encryption does and does not do. Encryption, when properly used, is a *read access control*. If used correctly, no one who lacks access to the encryption key can read the encrypted data. Encryption, however, is *not* a *write access control*; that is, it does not guarantee the integrity of the encrypted data. Counter mode and stream ciphers are subject to bit-flipping attacks, for instance. An attacker launches a bit-flipping attack by capturing a frame or datagram, changing one or more bits from 0 to 1 (or vice versa) and retransmitting the altered frame. The resulting frame decrypts to some result—the altered message decrypts to something—and if bits are flipped judiciously, the result can be intelligible. As a second example, cipher-block chaining mode is susceptible to cut-and-paste attacks, whereby the attack cuts the final few blocks from one message in a stream and uses them to overwrite the final blocks of a later stream. At most, one block decrypts to gibberish; if the attacker chooses the paste point judiciously, for example, so that it falls where the application ought to have random data anyway, this can be a powerful attack. The upshot is that even encrypted data needs an integrity mechanism to be effective, which leads us to the subject of defenses against forgeries.

Defending against Forgeries and Replays

Forgery and replay detection are usually treated together because replays are a special kind of forgery. We follow this tradition in our own discussion. Forgery detection, not eavesdropping protection, is the central concern for designs to secure network protocol. This is because every accepted forgery of an encrypted frame or datagram is a question whose answer can tell the adversary something about the encryption key or plaintext data. Just as one learns any subject in school, an attacker can learn about the encrypted stream or encryption key faster by asking questions rather than sitting back and passively listening.

Since eavesdropping is a passive attack, whereas creating forgeries is active, turning from the subject of eavesdropping to that of forgeries changes the security

goals subtly. Encryption has a security goal of prevention—to prevent the adversary from learning anything useful about the data that cannot be derived in other ways. The comparable security goal for forgeries would be to prevent the adversary from creating forgeries, which is not feasible. This is because any device with a transmitter appropriate for the medium can send forgeries by creating frames and datagrams using addresses employed by other parties. What is feasible is a form of asking forgiveness instead of permission: Prevent the adversary from creating *undetected* forgeries.

The cryptographic tool underlying forgery detection is called a *message authentication code*. Like an encryption scheme, a message authentication code consists of three operations: a *key generation* operation, a *tagging* operation, and a *verification* operation. Also like encryption, the key generation operation, which generates a symmetric key shared between the sender and receiver, is usually application specific. The tagging and verification operations, however, are much different from encrypt and decrypt.

The tagging operation takes the symmetric key, called an *authentication key*, and a message as input parameters and outputs a *tag*, which is a cryptographic checksum depending on the key and message to produce its output.

The verification operation takes three input parameters: the symmetric key, the message, and its tag. The verification algorithm recomputes the tag from the key and message and compares the result against the tag with the received message. If the two fail to match, the verify algorithm outputs a signal that the message is a forgery. If the input and locally computed tag match, the verify algorithm declares that the message is authenticated.

The conclusion drawn by the verify algorithm of a message authentication code is not entirely logically correct. Indeed, if the tag is n bits in length, an attacker could generate a random n bit string as its tag and it would have one chance in 2^n of being valid. A message authentication scheme is considered good if there are no polynomial time algorithms that are significantly better than random guessing at producing correct tags.

Message authentication codes are incorporated into network protocols in a manner similar to encryption. First, a sequence number is prepended to the data that is being forgery protected; the sequence number, we will see, is used to detect replays. Next, a message authentication code tagging operation is applied to the sequence number and message body to produce a tag. The tag is appended to the message, and a key identifier for the authentication key is prepended to the message. The message can then be sent. The receiver determines whether the message was a forgery by first finding the authentication key identified by the key identifier, then by checking the correctness of the tag using the message authentication code's verify operation. If these checks succeed, the receiver finally uses the sequence number to verify that the message is not a replay.

How does replay detection work? When the authentication key is established, the sender initializes to zero the counter that is used in the authenticated message. The receiver meanwhile establishes a replay window, which is a list of all recently received sequence numbers. The replay window is initially empty. To send a replay protected frame, the sender increments his counter by one and prepends this at the front of the data to be authenticated prior to tagging. The receiver extracts the counter value from the received message and compares this to the replay window. If the counter falls before the replay window, which means it is too old to be considered valid, the receiver flags the message as a replay. The receiver does the same thing if the counter is already represented in the replay window data structure. If the counter is greater than the bottom of the replay window and is a counter value that has not yet been received, the frame or datagram is considered "fresh" instead of a replay.

The process is simplest to illustrate for the MAC layer. Over a single MAC link it is ordinarily impossible for frames to be reordered, because only a single device can access the medium at a time; because of the speed of electrons or photons comprising the signals representing bits, at least some of the bits at the start of a frame are received prior to the final bits being transmitted (satellite links are an exception). If frames cannot be reordered by a correctly operating MAC layer, the replay window data structure records the counter for the last received frame, and the replay detection algorithm merely has to decide whether the replay counter value in a received frame is larger than that recorded in its replay window. If the counter is less than or equal to the replay window value, the frame is a forgery; otherwise it is considered genuine. 802.11i, 802.16, and 802.1ae all employ this approach to replay detection. This same approach can be used by a message authentication scheme operating above the transport layer, by protocols such as TLS and SSH (Secure Shell), since the transport eliminates duplicates and delivers bits in the order sent. The replay window is more complicated at the network layer, however, because some reordering is natural, given that the network reorders datagrams. Hence, for the network layer the replay window is usually sized to account for the maximum reordering expected in the "normal" Internet. IPsec uses this more complex replay window.

This works for the following reason: Every message is given a unique, incrementing sequence number in the form of its counter value. The transmitter computes the message authentication code tag over the sequence number and the message data. Since it is not feasible for a computationally bounded adversary to create a valid tag

for the data with probability significantly greater than $1/2^n$, a tag validated by the receiver implies that the message, including its sequence number, was created by the transmitter. The worst thing that could have happened, therefore, is that the adversary has delayed the message. However, if the sequence number falls within the replay window, the message could not have been delayed longer than reordering due to the normal operation of forwarding and traffic shaping within the Internet.

A replay detection scheme limits an adversary's opportunities to delete and to reorder messages. If a message does not arrive at its destination, its sequence number is never set in the receive window, so it can be declared a lost message. It is easy to track the percentage of lost messages, and if this exceeds some threshold, then communications become unreliable, but more important, the cause of the unreliability can be investigated. Similarly, messages received outside the replay window can also be tracked, and if the percentage becomes too high, messages are arriving out of order more frequently than might be expected from normal operation of the Internet, pointing to a configuration problem, an equipment failure, or an attack. Again, the cause of the anomaly can be investigated. Mechanisms like these are often how attacks are discovered in the first place. The important lesson is that attacks and even faulty equipment or misconfigurations are often difficult to detect without collecting reliability statistics, and the forgery detection mechanisms can provide some of the best reliability statistics available.

Just like encryption, the correctness of this analysis depends critically on the design enforcing some fundamental assumptions, regardless of the quality of the message authentication code on which it might be based. If any of the following assumptions are violated, the forgery detection scheme can fail catastrophically to accomplish its mission.

Independence of Authentication Keys

This is absolutely paramount for forgery detection. If the message authentication keys are not independent, an attacker can easily create forged message authentication tags based on authentication keys learned in other ways. This assumption is so important that it is useful to examine in greater detail.

The first point is that a message authentication key utterly fails to accomplish its mission if it is shared among even three parties; only two parties must know any particular authentication key. This is very easy to illustrate. Suppose A, B, and C were to share a message authentication key, and suppose A creates a forgery-protected message it sends to C. What can C conclude when it receives this message? C cannot conclude that the message actually originated from A, even though its addressing indicates it did, because B could have produced the same message and used A's address. C cannot even conclude that B did not change some of the message in transit. Therefore, the algorithm loses all its efficacy for detecting forgeries if message authentication keys are known by more than two parties. They must be known by at least two parties or the receiver cannot verify that the message and its bits originated with the sender.

This is much different than encryption. An encryption/decryption key can be distributed to every member of a group, and as long as the key is not leaked from the group to a third party, the encryption scheme remains an effective read access control against parties that are not members of the group. Message authentication utterly fails if the key is shared beyond two parties. This is due to the active nature of forgery attacks and the fact that forgery handling, being a detection rather than a prevention scheme, already affords the adversary more latitude than encryption toward fooling the good guys.

So for forgery detection schemes to be effective, message authentication keys must be shared between exactly two communicating devices. As with encryption keys, a message authentication key must be generated randomly because brute-force searches and related key attacks can recover the key by observing messages transiting the medium.

No Reuse of Replay Counter Values with a Key

Reusing a counter with a message authentication key is analogous to reusing an initialization vector with an encryption key. Instead of leaking data, however, replay counter value reuse leads automatically to trivial forgeries based on replayed messages. The attacker's algorithm is trivial: Using a packet sniffer, record each of the messages protected by the same key and file them in a database. If the attacker ever receives a key identifier and sequence number pair already in the database, the transmitter has begun to reuse replay counter values with a key. The attacker can then replay any message with a higher sequence number and the same key identifier. The receiver will be fooled into accepting the replayed message.

This approach implies that known forgery detection schemes cannot be based on static keys. To the contrary, we could attempt to design such a scheme. One could try to checkpoint in nonvolatile memory the replay counter at the transmitter and the replay window at the receiver. This approach does not work, however, in the presence of a Dolev–Yao adversary. The adversary can capture a forgery-protected frame in flight and then delete all successive messages. At its convenience later, the adversary resends the captured message. The receiver, using its static message authentication key, will verify the tag and, based on its replay window retrieved from nonvolatile

storage, verify that the message is indeed in sequence and so accept the message as valid. This experiment demonstrates that forgery detection is not entirely satisfactory because sequence numbers do not take timeliness into account. Secure clock synchronization, however, is a difficult problem with solutions that enjoy only partial success. The construction of better schemes that account for timing remains an open research problem.

Key Size

If message authentication keys must be randomly generated, they must also be of sufficient size to discourage brute-force attack. The key space has to be large enough to make exhaustive search for the message authentication key cost prohibitive. Key sizes for message authentication comparable with those for encryption are sufficient for this task.

Message Authentication Code Tag Size

We have seen many aspects that make message authentication codes somewhat more fragile encryption schemes. Message authentication code size is one in which forgery detection can on the contrary effectively utilize a smaller block size than an encryption scheme. Whereas an encryption scheme based on a 128-bit block size has to replace keys every 2^{48} or so blocks to avoid leaking data, an encryption scheme can maintain the same level of security with about a 48-bit message authentication code tag. The difference is that the block cipher-based encryption scheme leaks information about the encrypted data due to the birthday paradox, whereas an attacker has to create a valid forgery based on an exhaustive search due to the active nature of a forgery attack. In general, to determine the size of a tag needed by a message authentication code, we have only to determine the maximum number of messages sent in the lifetime of the key. As a rule of thumb, if this number of messages is bounded by 2^n, the tag need only be $n+1$ bits long. This is only a rule of thumb because some MACs cannot be safely truncated to this minimal number of bits.

As with encryption, for many it is confusing that forgery detection schemes are offered at nearly every layer of the Internet architecture. To understand the preceding concept, it is again useful to ask what message forgery detection accomplishes at each layer.

If a MAC module requires forgery detection for every frame received, physical access to the medium being used by the module's PHY layer affords an attacker no opportunity to create forgeries. This is a very strong property. It means that the only MAC layer messages attacking the receiver are either generated by other devices authorized to attach to the medium or else are forwarded by the network layer modules of authorized devices, because all frames received directly off the medium generated by unauthorized devices will be discarded by the forgery detection scheme. A MAC layer forgery detection scheme therefore essentially provides a write access control of the physical medium, closing it to unauthorized parties. Installing a forgery detection scheme at any other layer will not provide this kind of protection. Requiring forgery detection at the MAC layer is therefore desirable whenever feasible.

Forgery detection at the network layer provides a different kind of assurance. IPsec is the protocol designed to accomplish this function. If a network layer module requires IPsec for every datagram received, this essentially cuts off attacks against the device hosting the module to other authorized machines in the entire Internet; datagrams generated by unauthorized devices will be dropped. With this forgery detection scheme it is still possible for an attacker on the same medium to generate frames attacking the device's MAC layer module, but attacks against higher layers become computationally infeasible. Installing a forgery detection scheme at any other layer will not provide this kind of protection. Requiring forgery detection at the network layer is therefore desirable whenever feasible as well.

Applying forgery detection at the transport layer offers different assurances entirely. Forgery detection at this level assures the receiving application that the arriving messages were generated by the peer application, not by some virus or Trojan-horse program that has linked itself between modules between protocol layers on the same or different machine. This kind of assurance cannot be provided by any other layer. Such a scheme at the network or MAC layers only defends against message injection by unauthorized devices on the Internet generally or directly attached to the medium, not against messages generated by unauthorized processes running on an authorized machine. Requiring forgery detection at the transport layer therefore is desirable whenever it is feasible.

The conclusion is that forgery detection schemes accomplish different desirable functions at each protocol layer. The security goals that are achievable are always architecturally dependent, and this comes through clearly with forgery detection schemes.

We began the discussion of forgery detection by noting that encryption by itself is subject to attack. One final issue is how to use encryption and forgery protection together to protect the same message. Three solutions could be formulated to this problem. One approach might be to add forgery detection to a message first—add the authentication key identifier, the replay sequence number, and the message authentication code tag—followed by encryption of the message data and forgery detection headers. TLS is an example Internet protocol that takes this approach. The second approach is to reverse the order of encryption and forgery detection: First encrypt, then

compute the tag over the encrypted data and the encryption headers. IPsec is an example Internet protocol defined to use this approach. The last approach is to apply both simultaneously to the plaintext data. SSH is an Internet protocol constructed in this manner.

Session Start-up Defenses

If encryption and forgery detection techniques are such powerful security mechanisms, why aren't they used universally for all network communications? The problem is that not everyone is your friend; everyone has enemies, and in every human endeavor there are those with criminal mind-sets who want to prey on others. Most people do not go out of their way to articulate and maintain relationships with their enemies unless there is some compelling reason to do so, and technology is powerless to change this.

More than anything else, the keys used by encryption and forgery detection are relationship signifiers. Possession of keys is useful not only because they enable encryption and forgery detection but because their use assures the remote party that messages you receive will remain confidential and that messages the peer receives from you actually originated from you. They enable the accountable maintenance of a preexisting relationship. If you receive a message that is protected by a key that only you and I know, and you didn't generate the message yourself, it is reasonable for you to conclude that I sent the message to you and did so intentionally.

If keys are signifiers of preexisting relationships, much of our networked communications cannot be defended by cryptography, because we do not have preexisting relationships with everyone. We send and receive email to and from people we have never met. We buy products online from merchants we have never met. None of these relationships would be possible if we required all messages to be encrypted or authenticated. What is always required is an open, unauthenticated, risky channel to establish new relationships; cryptography can only assure us that communication from parties with whom we already have relationships is indeed occurring with the person with whom we think we are communicating.

A salient and central assumption for both encryption and forgery detection is that the keys these mechanisms use are fresh and independent across sessions. A session is an instance of exercising a relationship to effect communication. This means that secure communications require a state change, transitioning from a state in which two communicating parties are not engaged in an instance of communication to one in which they are. This state change is *session establishment*.

Session establishment is like a greeting between human beings. It is designed to synchronize two entities communicating over the Internet and establish and synchronize their keys, key identifiers, sequence numbers and replay windows, and, indeed, all the states to provide mutual assurance that the communication is genuine and confidential.

The techniques and data structures used to establish a secure session are different from those used to carry on a conversation. Our next goal is to look at some representative mechanisms in this area. The field is vast, and it is impossible to do more than skim the surface briefly to give the reader a glimpse of the beauty and richness of the subject. Secure session establishment techniques typically have three goals, as described in the following sections of this chapter.

Mutual Authentication

First, session establishment techniques seek to mutually authenticate the communicating parties to each other. *Mutually authenticate* means that both parties learn the "identity" of the other. It is not possible to know what is proper to discuss with another party without also knowing the identity of the other party. If only one party learns the identity of the other, it is always possible for an imposter to masquerade as the unknown party.

There are a couple of points to make about this issue. The first is what "learn" means. The kind of learning needed for session establishment is the creation of common knowledge: You know both identities, the peer knows both identities, and the peer knows you know both identities (and vice versa). A lower level of knowledge always enables opportunities for subverting the session establishment protocol.

The second point is what an identity is. Identities in session establishment protocols work differently than they do in real life. In session establishment, an identity is a commitment to a key that identifies you or your computing system. That is, an identity commits its sender to utilizing a particular key during session establishment, and the receiver to reject protocol messages generated using other keys.

Key Secrecy

Second, session establishment techniques seek to establish a session key that can be maintained as a secret between the two parties and is known to no one else. The session key must be independent from all other keys for all other session instances and indeed from all other keys. This implies that no adversary with limited computational resources can distinguish the key from one selected uniformly at random. Generating such an independent session key is both harder and easier than it sounds; it is always possible to do so if a preexisting relationship already exists between the two communicating parties,

and it is impossible to do so reliably if a preexisting relationship does not exist. Relationships begat other relationships, and nonrelationships are sterile with respect to the technology.

Session State Consistency

Finally, the parties need to establish a consistent view of the session state. This means that they both agree on the identities of both parties; they agree on the session key instance; they agree on the encryption and forgery detection schemes used, along with any associated state such as sequence counters and replay windows; and they agree on which instance of communication this session represents. If they fail to agree on a single shared parameter, it is always possible for an imposter to convince one of the parties that it is engaged in a conversation that is different from its peer's conversation. As with identities, agree means the two establish common knowledge of all of these parameters, and a session establishment protocol can be considered secure in the Dolev−Yao model only if the protocol proves that both parties share common knowledge of all of the parameters.

Mutual Authentication

There are an enormous number of ways to accomplish the mutual authentication function needed to initiate a new session. Here we examine two approaches that are used in various protocols within the Internet.

A Symmetric Key Mutual Authentication Method

Our old friend the message authentication code can be used with a static, long-lived key to create a simple and robust mutual authentication scheme. Earlier we stressed that the properties of message authentication are incompatible with the use of a static key to provide forgery detection of session-oriented messages. The incompatibility is due to the use of sequence numbers for replay detection. We will replace sequence numbers with unpredictable quantities in order to resocialize static keys. The cost of this resocialization effort will be a requirement to exchange extra messages.

Suppose parties A and B want to mutually authenticate. We will assume that ID_A is B's name for the key it shares with A, whereas ID_B is A's name for the same key B. We will also assume that A and B share a long-lived message authentication key K and that K is known only to A and B. We will assume that A initiates the authentication. A and B can mutually authenticate using a three-message exchange, as follows: For message 1, A generates a random number R_A and sends a message containing its identity ID_A and random number to B:

$$\mathrm{A} \rightarrow \mathrm{B}: ID_A,\ R_A \tag{1}$$

The notation $\mathrm{A} \rightarrow \mathrm{B}$: m means that A sends message m to B. Here the message being passed is specified as ID_A, R_A, meaning it conveys A's identity ID_A (or, more precisely, the name of the key K) and A's random number R_A. This message asserts B's name for A, to tell B which is the right long-lived key it should use in this instance of the authentication protocol. The random number R_A plays the role of the sequence number in the session-oriented case. It is random in order to provide an unpredictable challenge. If B responds correctly, then this proves that the response is live and was not pre-recorded. R_A also acts as a transaction identifier for the response to A's message 1 (it allows A to recognize which response goes with which message 1). This is important in itself, because without the ability to interleave different instances of the protocol A would have to wait forever for any lost message in order to obtain a correct theory.

If B is willing to have a conversation with A at this time, it fetches the correct message authentication key K, generates its own random number R_B, and computes a message authentication code tag T over the message ID_B, ID_A, R_A, R_B, that is, over the message consisting of both names and both random numbers. B appends the tag to the message, which it then sends to A in response to message 1:

$$\mathrm{B} \rightarrow A: ID_B,\ ID_A,\ R_A,\ R_B,\ T \tag{2}$$

B includes A's name in the message to tell A which key to use to authenticate the message. It includes A's random number R_A in the message to signal the protocol instance to which this message responds.

The magic begins when A validates the message authentication code tag T. Since independently generated random numbers are unpredictable, A knows that the second message could not have been produced before A sent the first, because it returns R_A to A. Since the authentication code tag T was computed over the two identities ID_B and ID_A and the two random numbers R_A and R_B using the key K known only to A and B, and since A did not create the second message itself, A knows that B must have created message 2. Hence, message 2 is a response from B to A's message 1 for this instance of the protocol. If the message were to contain some other random number than R_A, A would know the message is not a response to its message 1.

If A verifies message 2, it responds by computing a message authentication code tag T' computed over ID_A and B's random number RB, which it includes in message 3:

$$\mathrm{A} \rightarrow B: ID_A,\ R_B,\ T' \tag{3}$$

Reasoning as before, B knows A produced message 3 in response to its message 2, because message 3 could not have been produced prior to message 2 and only A could have produced the correct tag T'. Thus, after message 3 is delivered, A and B both have been assured

of each other's identity, and they also agree on the session instance, which is identified by the pair of random numbers R_A and R_B.

A deeper analysis of the protocol reveals that message 2 must convey both identities and both random numbers protected from forgery by the tag *T*. This construction binds A's view of the session with B's, and this is providing A with B's view of what they know in common. This binding prevents interleaving or man-in-the-middle attacks. As an example, without this binding, a third party, C, could masquerade as B to A and as A to B. Similarly, message 3 confirms the common knowledge: A knows that B knows that A knows ID_A, ID_B, R_A, and R_B if B verifies the third message; similarly, if B verifies message 3, B knows that A knows that B knows the same parameters.

It is worth noting that message 1 is not protected from either forgery or replay. This lack of any protection is an intrinsic part of the problem statement. During the protocol, A and B must transition from a state where they are unsure about the other's identity and have no communication instance instantiating the long-term relationship signified by the encryption key *K* to a state where they fully agree on each other's identities and a common instance of communication expressing their long-lived relationship. A makes the transition upon verifying message 2, and there are no known ways to reassure it about B until this point of the protocol. B makes the state transition once it has completed verification of message 3. The point of the protocol is to transition from a mutually suspicious state to a mutually trusted state.

An Asymmetric Key Mutual Authentication Method

Authentication based on asymmetric keys is also possible. In addition to asymmetric encryption, there is also an asymmetric key analog of a message authentication code called a *signature scheme*. Just like a message authentication code, a signature scheme consists of three operations: *key generate*, *sign*, and *verify*. The key generate operation outputs two parameters, a signing key *S* and a related verification key *V*. *S*'s key holder is never supposed to reveal *S* to another party, whereas *V* is meant to be a public value. Under these assumptions, the sign operation takes the signing key *S* and a message *M* as input parameters and outputs a signature *s* of *M*. The verify operation takes the verification key *V*, message *M*, and signature *s* as inputs, and returns whether it verifies that *s* was created from *S* and *M*. If the signing key *S* is indeed known by only one party, the signature *s* must have been produced by that party. This is because it is infeasible for a computationally limited party to compute the signature *s* without *S*. Asymmetric signature schemes are often called *public/private key schemes* because *S* is maintained as a secret, never shared with another party, whereas the verification key is published to everyone.

Signature schemes were invented to facilitate authentication. To accomplish this goal, the verification key must be public, and it is usually published in a certificate, which we will denote as $cert(ID_A, V)$, where ID_A is the identity of the key holder of *S* and *V* is the verification key corresponding to *A*. The certificate is issued by a well-known party called a *certificate authority*. The sole job of the certificate authority is to introduce one party to another. A certificate $cert(ID_A, V)$ issued by a certificate authority is an assertion that entity A has a public verification key *V* that is used to prove A's identity.

As with symmetric authentication, hundreds of different authentication protocols can be based on signature schemes. The following is one example among legions of examples:

$$\mathrm{A} \rightarrow B\colon cert(ID_A, V),\ R_A \tag{4}$$

Here $cert(ID_A, V)$ is A's certificate, conveying its identity ID_A and verification key *V;* R_A is a random number generated by A. If B is willing to begin a new session with A, it responds with the message:

$$\mathrm{B} \rightarrow A\colon cert(ID_B, V'),\ R_B,\ R_A, \mathrm{sig}_B(ID_A,\ R_B,\ R_A) \tag{5}$$

R_B is a random number generated by B, and $sig_B\ (ID_A, R_B, R_A)$ is B's signature over the message with fields ID_A, R_B, and R_A. Including IDA under B's signature is essential because it is B's way of asserting that A is the target of message 2. Including *RB* and *RA* in the information signed is also necessary to defeat man-in-the-middle attacks. A responds with a third message:

$$A \rightarrow B\colon cert(ID_A, V),\ R_b, sig_B(ID_B,\ R_B) \tag{6}$$

A Caveat

Mutual authentication is necessary to establish identities. Identities are needed to decide on the access control policies to apply to a particular conversation, that is, to answer the question, Which information that the party knows is suitable for sharing in the context of this communications instance? Authentication—mutual or otherwise—has very limited utility if the communications channel is not protected against eavesdropping and forgeries.

One of the most common mistakes made by Wi-Fi hotspot operators, for instance, is to require authentication but disable eavesdropping and forgery protection for the subsequent Internet access via the hotspot. This is because anyone with a Wi-Fi radio transmitter can access the medium and hijack the session from a paying customer. Another way of saying this is that authentication is useful only when it's used in conjunction with a

secure channel. This leads to the topic of session key establishment. The most common use of mutual authentication is to establish ephemeral session keys using the long-lived authentication keys. We will discuss session key establishment next.

Key Establishment

Since it is generally infeasible for authentication to be meaningful without a subsequent secure channel, and since we know how to establish a secure channel across the Internet if we have a key, the next goal is to add key establishment to mutual authentication protocols. In this model, a mutual authentication protocol establishes an ephemeral session key as a side effect of its successful operation; this session key can then be used to construct all the encryption and authentication keys needed to establish a secure channel. All the session states, such as sequence number, replay windows, and key identifiers, can be initialized in conjunction with the completion of the mutual authentication protocol.

It is usually feasible to add key establishment to an authentication protocol. Let's illustrate this with the symmetric key authentication protocol, based on a message authentication code, discussed previously. To extend the protocol to establish a key, we suppose instead that A and B share two long-lived keys K and K'.The first key K is a message authentication key as before. The second key K' is a derivation key, the only function of which is to construct other keys within the context of the authentication protocol. This is accomplished as follows: After verifying message 2 (from line 2 previously), A computes a session key SK as:

$$SK \leftarrow prf(K', R_A, R_B, ID_A, ID_B, length) \qquad (7)$$

Here *prf* is another cryptographic primitive called a *pseudorandom function*. A pseudorandom function is characterized by the properties that (a) its output is indistinguishable from random by any computationally limited adversary and (b) it is hard to invert; that is, given a fixed output O, it is infeasible for any computationally limited adversary to find an input I so that $O \leftarrow prf(I)$. The output SK of (7) is *length* bits long and can be split into two pieces to become encryption and message authentication keys. B generates the same SK when it receives message 3. An example of a pseudorandom function is any block cipher, such as AES, in cipher-block chaining MAC mode. Cipher-block chaining MAC mode is just like cipher-block chaining mode, except all but the last block of encrypted data is discarded.

This construction meets the goal of creating an independent, ephemeral set of encryptions of message authentication keys for each session. The construction creates independent keys because any two outputs of a *prf* appear to be independently selected at random to any adversary that is computationally limited. A knows that all the outputs are statistically distinct, because A picks the parameter to the prf R_A randomly for each instance of the protocol; similarly for B. And using the communications instances identifiers RA, RB along with A and B's identities ID_A and ID_B are interpreted as a "contract" to use SK only for this session instance and only between A and B.

Public key versions of key establishment based on signatures and asymmetric encryption also exist, but we will close with one last public key variant based on a completely different asymmetric key principle called the *Diffie–Hellman algorithm.*

The Diffie–Hellman algorithm is based on the discrete logarithm problem in finite groups. A group G is a mathematical object that is closed under an associative multiplication and has inverses for each element in G. The prototypical example of a finite group is the integers under addition modulo a prime number p.

The idea is to begin with an element g of a finite group G that has a long period. This means $g^1 = g$, $g^2 = g$ X g, $g^3 = g^2$ X g, ... Since G is finite, this sequence must eventually repeat. It turns out that $g = g^{n+1}$ for some integer $n > 1$, and $g^n = e$ is the group's neutral element. The element e has the property that h X $e = e$ X $h = h$ *for* every element h in G, and n is called the *period* of g. With such an element it is easy to compute powers of g, but it is hard to compute the logarithm of g^k. If g is chosen carefully, no polynomial time algorithm is known that can compute k from g^k. This property leads to a very elegant key agreement scheme:

$$A \rightarrow B: cert(ID_A, V), g^a$$
$$B \rightarrow A: g^b, cert(ID_B, V'), sig_B(g^a, g^b, ID_A)$$
$$A \rightarrow B: sig_A(g^b, g^a, ID_B)$$

The session key is then computed as SK ← prf(K, $g^a g^b$, ID_A, ID_B), where K ← prf(0, g^{ab}). In this protocol, a is a random number chosen by A, b is a random number chosen by B, and 0 denotes the all zeros key. Note that A sends g^a unprotected across the channel to B.

The quantity g^{ab} is called the *Diffie–Hellman key*. Since B knows the random secret b, it can compute $g^{ab} = (g^a)^b$ from A's public value g^a, and similarly A can compute g^{ab} from B's public value g^b. This construction poses no risk, because the discrete logarithm problem is intractable, so it is computationally infeasible for an attacker to determine a from g^a. Similarly, B may send g^b across the channel in the clear, because a third party cannot extract b from g^b. B's signature on message 2 prevents forgeries and assures that the response is from B. Since no method is known to compute g^{ab} from g^a and g^b, only A and B will know the Diffie–Hellman key at the end of the protocol. The step $K \leftarrow prf(0, g^{ab})$ extracts all

An Agenda for Action in Selecting Internet Security Process Activities

The following high-level checklist should be addressed in order to find the following Internet security practices helpful (check all tasks completed):

_____**1.** Login pages should be encrypted.
_____**2.** Data validation should be done server-side.
_____**3.** Manage your Web site via encrypted connections.
_____**4.** Use strong, cross-platform compatible encryption.
_____**5.** Connect from a secured network.
_____**6.** Don't share login credentials.
_____**7.** Prefer key-based authentication over password authentication.
_____**8.** Maintain a secure workstation.
_____**9.** Use redundancy to protect the Web site.
_____**10.** Make sure you implement strong security measures that apply to all systems — not just those specific to Web security.
_____**11.** Validate logins trough SSL encryption.
_____**12.** Do not use clear text protocols to manage your server.
_____**13.** Implement security policies that apply to all systems.

the computational entropy from the Diffie–Hellman key. The construction $SK \leftarrow prf(K, g^a g^b, ID_A, ID_B)$ computes a session key, which can be split into encryption and message authentication keys as before.

The major drawback of Diffie–Hellman is that it is subject to man-in-the-middle attacks. The preceding protocol uses signatures to remove this threat. B's signature authenticates B to a and also binds g^a and g^b together, preventing man-in-the-middle attacks. Similarly, A's signature on message 3 assures B that the session is with A.

These examples illustrate that it is practical to construct session keys that meet the requirements for cryptography, if a long-lived relationship already exists.

State Consistency

We have already observed that the protocol specified in (1) through (3) achieves state consistency when the protocol succeeds. Both parties agree on the identities and on the session instance. When a session key SK is derived, as in (7), both parties also agree on the key. Determining which parties know which pieces of information after each protocol message is the essential tool for a security analysis of this kind of protocol. The analysis of this protocol is typical for authentication and key establishment protocols.

Finally, allowing Internet access in the workplace can create two challenges: ensuring employee efficiency and mitigating security risks. Since you can't simply take away Internet privileges, you must find a way to boost employee productivity while maintaining Internet security. So, with the preceding in mind, because of the frequency of poor security practices or far-too-common security failures on the Internet, let's briefly look at the importance of the process that is used to gather all of these faults into an Internet security checklist and give them a suitable solution.

4. INTERNET SECURITY CHECKLIST

Internet security is a fast-moving challenge and an ever-present threat. There is no one right way to secure a Web site, and all security methods are subject to instant obsolescence, incremental improvement, and constant revision. All public facing Web sites are open to constant attack. So, are you willing and able to invest the time it takes to administer a dynamic, 24×7, world-accessible, database-driven, interactive, user-authenticated Web site? Do you have the time and resources to respond to the constant flow of new Internet security issues? The following high- level checklist helps to answer the preceding questions and addresses a number of far-too-common security failures on the Internet (see checklist: An Agenda for Action in Selecting Internet Security Process Activities).

5. SUMMARY

This chapter examined how cryptography is used on the Internet to secure protocols. It reviewed the architecture of the Internet protocol suite, for even the meaning of what security means is a function of the underlying system architecture. Next it reviewed the Dolev–Yao model, which describes the threats to which network communications are exposed. In particular, all levels of network protocols are completely exposed to eavesdropping and manipulation by an attacker, so using cryptography properly is a first-class requirement to derive any benefit from its use. We learned that effective security mechanisms to protect session-oriented and session establishment protocols are different, although they can share many cryptographic primitives. Cryptography can be very successful in protecting messages on the Internet, but doing so requires preexisting, long-lived relationships. How to build secure open communities is still an open problem; it is probably an intractable question because a solution

would imply the elimination of conflict between human beings who do not know each other.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? The Internet was designed to create standardized communication between computers.
2. True or False? Since communication is an extremely complex activity, it should come as no surprise that the system components providing communication decompose into modules.
3. True or False? Practical solutions addressing Byzantine failures fall largely within the purview of platform rather than network architecture, although the interconnectivity topology is an important consideration.
4. True or False? Security analyses of systems traditionally begin with a model of the user.
5. True or False? A user can eavesdrop on a communications medium by connecting a receiver to the medium.

Multiple Choice

1. The Internet supports message exchange through a mechanism called:
   A. interfaces.
   B. send primitive.
   C. protocols.
   D. confirm primitive.
   E. listen primitive.
2. A minimal communications service interface requires the following four primitives, except which one?
   A. Send
   B. Clear
   C. Confirm
   D. Listen
   E. Receive
3. A report of diagnostic and performance information about underlying communications is known as a:
   A. send primitive.
   B. confirm primitive.
   C. shift cipher.
   D. status primitive.
   E. deliver primitive.
4. What is technically not part of the Internet architecture per se?
   A. PHY Layer
   B. Chi-square statistic
   C. Polyalphabetic cipher
   D. Kerckhoff's principle
   E. Unicity distance
5. What is a request/response protocol designed to determine the reachability of another IP address?
   A. Traceroute
   B. Chisquare test
   C. Statistical test
   D. Ping
   E. Destination unreachable

Chapter 12

The Botnet Problem

Daniel Ramsbrock
George Mason University

Xinyuan Wang
George Mason University

A *botnet* is a collection of compromised Internet computers being controlled remotely by attackers for malicious and illegal purposes. The term comes from programs that are called *robots*, or *bots* for short, because of their automated behavior.

Bot software is highly evolved Internet malware, incorporating components of viruses, worms, spyware, and other malicious software. The person controlling a botnet is known as the *botmaster* or *bot-herder*; and he or she seeks to preserve that person's anonymity at all costs. Unlike previous malware such as viruses and worms, the motivation for operating a botnet is financial. Botnets are extremely profitable, earning their operators hundreds of dollars per day. Botmasters can either rent botnet processing time to others or make direct profits by sending spam, distributing spyware to aid in identity theft, and even extorting money from companies via the threat of a distributed denial-of-service (DDoS) attack.[1] It is no surprise that many network security researchers believe that botnets are one of the most pressing security threats on the Internet today.

Bots are at the center of the undernet economy. Almost every major crime problem on the Net can be traced to them.

—Jeremy Linden, formerly of Arbor Networks[2]

1. INTRODUCTION

You sit down at your computer in the morning, still squinting from sleep. Your computer seems a little slower than usual, but you don't think much of it. After checking the news, you try to sign into eBay to check on your auctions. Oddly enough, your password doesn't seem to work. You try a few more times, thinking maybe you changed it recently—but without success.

Figuring you'll look into it later, you sign into online banking to pay some of those bills that have been piling up. Luckily, your favorite password still works there—so it must be a temporary problem with eBay. Unfortunately, you are in for more bad news: The $0.00 balance on your checking and savings accounts isn't just a "temporary problem." Frantically clicking through the pages, you see that your accounts have been completely cleaned out with wire transfers to several foreign countries.

You check your email, hoping to find some explanation of what is happening. Instead of answers, you have dozens of messages from "network operations centers" around the world, informing you in no uncertain terms that your computer has been scanning, spamming, and sending out massive amounts of traffic over the past 12 hours or so. Shortly afterward, your Internet connection stops working altogether, and you receive a phone call from your service provider. They are very sorry, they explain, but due to something called "botnet activity" on your computer, they have temporarily disabled your account. Near panic now, you demand an explanation from the network technician on the other end. "What exactly is a botnet? How could it cause so much damage overnight? "

Although this scenario might sound far-fetched, it is entirely possible; similar things have happened to thousands of people over the last few years. Once a single bot program is installed on a victim computer, the possibilities are nearly endless. For example, the attacker can get your online passwords, drain your bank accounts, and use your computer as a remote-controlled "zombie" to scan for other victims, send out spam emails, and even launch DDoS attacks.

2. S. Berinato, "Attack of the Bots," *WIRED*, 14(11), November 2006, www.wired.com/wired/archive/14.11/botnet.html.

This chapter describes the botnet threat and the countermeasures available to network security professionals. First, it provides an overview of botnets, including their origins, structure, and underlying motivation. Next, the chapter describes existing methods for defending computers and networks against botnets. Finally, it addresses the most important aspect of the botnet problem: how to identify and track the botmaster in order to eliminate the root cause of the botnet problem.

2. BOTNET OVERVIEW

Bots and botnets are the latest trend in the evolution of Internet malware. Their black-hat developers have built on the experience gathered from decades of viruses, worms, Trojan horses, and other malware to create highly sophisticated software that is difficult to detect and remove. Typical botnets have several hundred to several thousand members, though some botnets have been detected with over 5.9 million members.[3] As of January 2011, industry analysts estimated that up to 590 million computers (about 36 percent of all Internet hosts) were infected with bot software.[4]

Origins of Botnets

Before botnets, the main motivation for Internet attacks was fame and notoriety. By design, these attacks were noisy and easily detected. High-profile examples are the Melissa email worm (1999), ILOVEYOU (2000), Code Red (2001), Slammer (2003), and Sasser (2004).[5] Although the impact of these viruses and worms was severe, the damage was relatively short-lived and consisted mainly of the cost of the outage plus man-hours required for cleanup. Once the infected files had been removed from the victim computers and the vulnerability patched, the attackers no longer had any control.

By contrast, botnets are built on the very premise of extending the attacker's control over his victims. To achieve long-term control, a bot must be stealthy during every part of its life cycle, unlike its predecessors.[2] As a result, most bots have a relatively small network footprint and do not create much traffic during typical operation. Once a bot is in place, the only required traffic consists of incoming commands and outgoing responses, constituting the botnet's command and control (C&C) channel. Therefore, the scenario at the beginning of the chapter is not typical of all botnets. Such an obvious attack points to either a brazen or an inexperienced botmaster, and there are plenty of them.

The concept of a remote-controlled computer bot originates from Internet Relay Chat (IRC), where benevolent bots were first introduced to help with repetitive administrative tasks such as channel and nickname management.[1,2] One of the first implementations of such an IRC bot was Eggdrop, originally developed in 1993 and still one of the most popular IRC bots.[6] Over time, attackers realized that IRC was in many ways a perfect medium for large-scale botnet C&C. It provides an instantaneous one-to-many communications channel and can support very large numbers of concurrent users.[6]

Botnet Topologies and Protocols

In addition to the traditional IRC-based botnets, several other protocols and topologies have emerged recently. The two main botnet topologies are centralized and peer-to-peer (P2P). Among centralized botnets, IRC is still the predominant protocol,[7,8,9] but this trend is decreasing and several recent bots have used HTTP for their C&C channels.[7,9] Among P2P botnets, many different protocols exist, but the general idea is to use a decentralized collection of peers and thus eliminate the single point of failure found in centralized botnets. P2P is becoming the most popular botnet topology because it has many advantages over centralized botnets.[10]

Centralized

Centralized botnets use a single entity (a host or a small collection of hosts) to manage all bot members. The advantage of a centralized topology is that it is fairly easy to implement and produces little overhead. A major disadvantage is that the entire botnet becomes useless if the central entity is removed, since bots will attempt to

connect to nonexistent servers. To provide redundancy against this problem, many modern botnets rely on dynamic DNS services and/or fast-flux DNS techniques. In a fast-flux configuration, hundreds or thousands of compromised hosts are used as proxies to hide the identities of the true C&C servers. These hosts constantly alternate in a round-robin DNS configuration to resolve one hostname to many different IP addresses (none of which are the true IPs of C&C servers). Only the proxies know the true C&C servers, forwarding all traffic from the bots to these servers.[11]

As we've described, the IRC protocol is an ideal candidate for centralized botnet control, and it remains the most popular among in-the-wild botmasters,[7,8,9] although it appears that will not be true much longer. Popular examples of IRC bots are Agobot, Spybot, and Sdbot.[11] Variants of these three families make up most active botnets today. By its nature, IRC is centralized and allows nearly instant communication among large botnets. One of the major disadvantages is that IRC traffic is not very common on the Internet, especially in an enterprise setting. As a result, standard IRC traffic can be easily detected, filtered, or blocked. For this reason, some botmasters run their IRC servers on nonstandard ports. Some even use customized IRC implementations, replacing easily recognized commands such as JOIN and PRIVMSG with other text. Despite these countermeasures, IRC still tends to stick out from the regular Web and email traffic due to uncommon port numbers.

Recently, botmasters have started using HTTP to manage their centralized botnets. The advantage of using regular Web traffic for C&C is that it must be allowed to pass through virtually all firewalls, since HTTP comprises a majority of Internet traffic. Even closed firewalls that only provide Web access (via a proxy service, for example) will allow HTTP traffic to pass. It is possible to inspect the content and attempt to filter out malicious C&C traffic, but this is not feasible due to the large number of existing bots and variants. If botmasters use HTTPS (HTTP encrypted using SSL/TLS), then even content inspection becomes useless and all traffic must be allowed to pass through the firewall. However, a disadvantage of HTTP is that it does not provide the instant communication and built-in, scale-up properties of IRC: Bots must manually poll the central server at specific intervals. With large botnets, these intervals must be large enough and distributed well to avoid overloading the server with simultaneous requests. Examples of HTTP bots are Bobax[12] and Rustock, with Rustock using a custom encryption scheme on top of HTTP to conceal its C&C traffic.[13]

Peer-To-Peer

As defenses against centralized botnets have become more effective, more and more botmasters are exploring ways to avoid the pitfalls of relying on a centralized architecture and therefore a single point of failure. Symantec reports a "steady decrease" in centralized IRC botnets and predicts that botmasters are now "accelerating their shift ... to newer, stealthier control methods, using protocols such as ... peer-to-peer."[10] In the P2P model, no centralized server exists, and all member nodes are equally responsible for passing on traffic. "If done properly, [P2P] makes it near impossible to shut down the botnet as a whole. It also provides anonymity to the [botmaster], because they can appear as just another node in the network," says security researcher Joe Stewart of Lurhq.[14] There are many protocols available for P2P networks, each differing in the way nodes first join the network and the role they later play in passing traffic along. Some popular protocols are BitTorrent, WASTE, and Kademlia.[11] Many of these protocols were first developed for benign uses, such as P2P file sharing.

One of the first malicious P2P bots was Sinit, released in September 2003. It uses random scanning to find peers, rather than relying on one of the established P2P bootstrap protocols.[11] As a result, Sinit often has trouble finding peers, which results in overall poor connectivity.[15] Due to the large amount of scanning traffic, this bot is easily detected by intrusion detection systems (IDSs).[16]

Another advanced bot using the P2P approach is Nugache, released in April 2006.[11] It initially connects to a list of 22 predefined peers to join the P2P network, then downloads a list of active peer nodes from there. This implies that if the 22 "seed" hosts can be shut down, no new bots will be able to join the network, but existing nodes can still function.[17] Nugache encrypts all

communications, making it harder for IDSs to detect and increasing the difficulty of manual analysis by researchers.[14] Nugache is seen as one of the first of the more sophisticated P2P bots, paving the way for future enhancements by botnet designers.

The most famous P2P bot so far is Peacomm, more commonly known as the Storm Worm. It started spreading in January 2007 and continues to have a strong presence. To communicate with peers, it uses the Overnet protocol, based on the Kademlia P2P protocol. For bootstrapping, it uses a fixed list of peers (146 in one observed instance) distributed along with the bot. Once the bot has joined Overnet, the botmaster can easily update the binary and add components to extend its functionality. Often the bot is configured to automatically retrieve updates and additional components, such as an Simple Mail Transfer Protocol (SMTP) server for spamming, an email address harvesting tool, and a DoS module. Like Nugache, all of Peacomm's communications are encrypted, making it extremely hard to observe C&C traffic or inject commands appearing to come from the botmaster. Unlike centralized botnets relying on a dynamic DNS provider, Peacomm uses its own P2P network as a distributed DNS system that has no single point of failure. The fixed list of peers is a potential weakness, although it would be challenging to take all these nodes offline. Additionally, the attackers can always set up new nodes and include an updated peer list with the bot, resulting in an "arms race" to shut down malicious nodes.[11]

3. TYPICAL BOT LIFE CYCLE

Regardless of the topology being used, the typical life cycle of a bot is similar:

1. *Creation.* First, the botmaster develops his bot software, often reusing existing code and adding custom features. He might use a test network to perform dry runs before deploying the bot in the wild.
2. *Infection.* There are many possibilities for infecting victim computers, including the following four. Once a victim machine becomes infected with a bot, it is known as a *zombie*.
   - Software vulnerabilities. The attacker exploits a vulnerability in a running service to automatically gain access and install his/her software without any user interaction. This was the method used by most worms, including the infamous Code Red and Sasser worms.[5]
   - *Drive-by download*. The attacker hosts his file on a Web server and entices people to visit the site. When the user loads a certain page, the software is automatically installed without user interaction, usually by exploiting browser bugs, misconfigurations, or unsecured ActiveX controls.
   - *Trojan horse*. The attacker bundles his malicious software with seemingly benign and useful software, such as screen savers, antivirus scanners, or games. The user is fully aware of the installation process, but he does not know about the hidden bot functionality.
   - *Email attachment*: Although this method has become less popular lately due to rising user awareness, it is still around. The attacker sends an attachment that will automatically install the bot software when the user opens it, usually without any interaction. This was the primary infection vector of the ILOVEYOU email worm from 2000.[5] The recent Storm Worm successfully used enticing email messages with executable attachments to lure its victims.[18]
3. *Rallying*. After infection, the bot starts up for the first time and attempts to contact its C&C server(s) in a process known as *rallying*. In a centralized botnet, this could be an IRC or HTTP server, for example. In a P2P botnet, the bots perform the bootstrapping protocol required to locate other peers and join the network. Most bots are very fault-tolerant, having multiple lists of backup servers to attempt if the primary ones become unavailable. Some C&C servers are configured to immediately send some initial commands to the bot (without botmaster intervention). In an IRC botnet, this is typically done by including the commands in the C&C channel's topic.
4. *Waiting.* Having joined the C&C network, the bot waits for commands from the botmaster. During this time, very little (if any) traffic passes between the victim and the C&C servers. In an IRC botnet, this traffic would mainly consist of periodic keep-alive messages from the server.
5. *Executing.* Once the bot receives a command from the botmaster, it executes it and returns any results to the botmaster via the C&C network. The supported commands are only limited by the botmaster's imagination and technical skills. Common commands are in line with the major uses of botnets: scanning for new victims, sending spam, sending DoS floods, setting up traffic redirection, and many more.

Following the execution of a command, the bot returns to the waiting state to await further instructions. If the victim computer is rebooted or loses its connection to the C&C network, the bot resumes in the rallying state. Assuming it can reach its C&C network, it will then continue in the waiting state until further commands arrive.

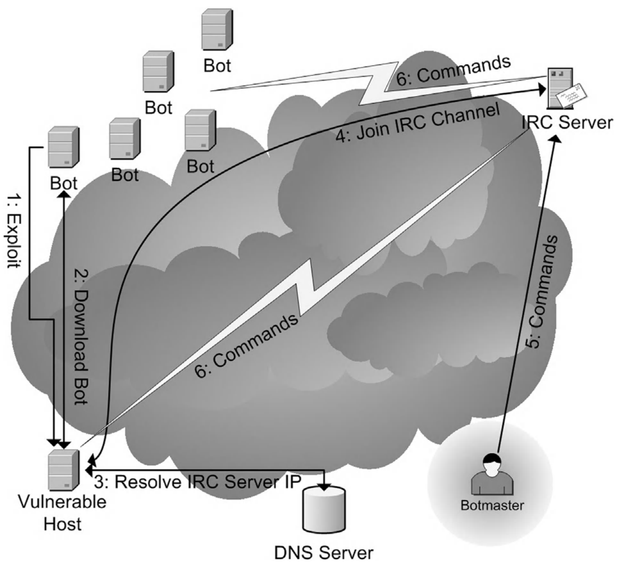

FIGURE 12.1 Infection sequence of a typical centralized IRC-based botnet.

Figure 12.1 shows the detailed infection sequence in a typical IRC-based botnet:

1. An existing botnet member computer launches a scan, then discovers and exploits a vulnerable host.
2. Following the exploit, the vulnerable host is made to download and install a copy of the bot software, constituting an infection.
3. When the bot starts up on the vulnerable host, it enters the rallying state: It performs a DNS lookup to determine the current IP of its C&C server.
4. The new bot joins the botnet's IRC channel on the C&C server for the first time, now in the waiting state.
5. The botmaster sends his commands to the C&C server on the botnet's IRC channel.
6. The C&C server forwards the commands to all bots, which now enter the executing state.

4. THE BOTNET BUSINESS MODEL

Unlike the viruses and worms of the past, botnets are motivated by financial profit. Organized crime groups often use them as a source of income, either by hiring "freelance" botmasters or by having their own members create botnets. As a result, network security professionals are up against motivated, well-financed organizations that can often hire some of the best minds in computers and network security. This is especially true in countries such as Russia, Romania, and other eastern European nations where there is an abundance of IT talent at the high school and university level but legitimate IT job prospects are very limited. In such an environment, criminal organizations easily recruit recent graduates by offering far better opportunities than the legitimate job market.[18–21] One infamous example of such a crime organization is the Russian Business Network (RBN), a Russian Internet service provider (ISP) that openly supports criminal activity.[19] They are responsible for the Storm Worm (Peacomm), the March 2007 DDoS attacks on Estonia, and a high-profile attack on the Bank of India in August 2007,[22] along with many other attacks.

It might not be immediately obvious how a collection of computers can be used to cause havoc and produce large profits. The main point is that botnets provide *anonymous* and *distributed* access to the Internet. The anonymity makes the attackers untraceable, and a botnet's distributed nature makes it extremely hard to shut down. As a result, botnets are perfect vehicles for criminal activities on the Internet. Some of the main profit-producing methods are explained here,[23] but criminals are always devising new and creative ways to profit from botnets:

- *Spam.* Spammers send millions of emails advertising phony or overpriced products, phishing for financial data and login information, or running advance-fee schemes such as the Nigerian 419 scam. Even if only a small percentage of recipients respond to this spam, the payoff is considerable for the spammer. It is estimated that up to 90 percent of all spam originates from botnets.[2]
- *DDoS and extortion.* Having amassed a large number of bots, the attacker contacts an organization and threatens to launch a massive DDoS attack, shutting down its Web site for several hours or even days. Another variation on this method is to find vulnerabilities, use them to steal financial or confidential data, and then demand money for the "safe return" of the data and to keep it from being circulated in the underground economy.[21] Often, companies would rather pay off the attacker to avoid costly downtime, lost sales, and the lasting damage to its reputation that would result from a DDoS attack or data breach.

23. P. Bächer, T. Holz, M. Kötter, and G. Wicherski, "Know Your Enemy: Tracking Botnets," March 13, 2005; see www.honeynet.org/papers/bots.

- *Identity theft.* Once a bot has a foothold on a victim's machine, it usually has complete control. For example, the attacker can install keyloggers to record login and password information, search the hard drive for valuable data, or alter the DNS configuration to redirect victims to look-alike Web sites and collect personal information, known as *pharming*. Using the harvested personal information, the attacker can make fraudulent credit-card charges, clean out the victim's bank account, and apply for credit in the victim's name, among many other things.
- *Click fraud.* In this scenario, bots are used to repeatedly click Web advertising links, generating per-click revenue for the attacker.[2] This represents fraud because only the clicks of human users with a legitimate interest are valuable to advertisers. The bots will not buy the product or service as a result of clicking the advertisement.

These illegal activities are extremely profitable. For example, a 2006 study by the Germany Honeynet Project estimated that a botmaster can make about $430 per day just from per-install advertising software.[24] A 20-year-old California botmaster indicted in February 2006 earned $100,000 in advertising revenue from his botnet operations.[25] However, both of these cases pale in comparison to the estimated $20 million worth of damage caused by an international ring of computer criminals known as the A-Team.[26]

Due to these very profitable uses of botnets, many botmasters make money simply by creating botnets and then renting out processing power and bandwidth to spammers, extortionists, and identity thieves. Despite a recent string of high-profile botnet arrests, these are merely a drop in the bucket.[4] Overall, botmasters still have a fairly low chance of getting caught due to a lack of effective traceback techniques. The relatively low risk combined with high yield makes the botnet business very appealing as a fundraising method for criminal enterprises, especially in countries with weak computer crime enforcement.

5. BOTNET DEFENSE

When botnets emerged, the response was similar to previous Internet malware: Antivirus vendors created signatures and removal techniques for each new instance of the bot. This approach initially worked well at the host level, but researchers soon started exploring more advanced methods for eliminating more than one bot at a time. After all, a botnet with tens of thousands of members would be very tedious to combat one bot at a time.

This part of the chapter describes the current defenses against centralized botnets, moving from the host level to the network level, then to the C&C server, and finally to the botmaster himself.

Detecting and Removing Individual Bots

Removing individual bots does not usually have a noticeable impact on the overall botnet, but it is a crucial first step in botnet defense. The basic antivirus approach using signature-based detection is still effective with many bots, but some are starting to use polymorphism, which creates unique instances of the bot code and evades signature-based detection. For example, Agobot is known to have thousands of variants, and it includes built-in support for polymorphism to change its signature at will.

To deal with these more sophisticated bots and all other polymorphic malware, detection must be done using behavioral analysis and heuristics. Researchers Stinson and Mitchell have developed a taint-based approach called BotSwat that marks all data originating from the network. If this data is used as input for a system call, there is a high probability that it is bot-related behavior, since user input typically comes from the keyboard or mouse on most end-user systems.[27]

Detecting C&C Traffic

To mitigate the botnet problem on a larger scale, researchers turned their attention to network-based detection of the botnet's C&C traffic. This method allows organizations or even ISPs to detect the presence of bots on their entire network, rather than having to check each machine individually.

One approach is to examine network traffic for certain known patterns that occur in botnet C&C traffic. This is, in effect, a network-deployed version of signature-based detection, where signatures have to be collected for each bot before detection is possible. Researchers Goebel and Holz implemented this method in their Rishi tool, which evaluates IRC nicknames for likely botnet membership based on a list of known botnet naming schemes. As with all signature-based approaches, it often leads to an "arms race" where the

attackers frequently change their malware and the network security community tries to keep up by creating signatures for each new instance.[28]

Rather than relying on a limited set of signatures, it is also possible to use the IDS technique of anomaly detection to identify unencrypted IRC botnet traffic. This method was successfully implemented by researchers Binkley and Singh at Portland State University, and as a result they reported a significant increase in bot detection on the university network.[29]

Another IDS-based detection technique called BotHunter was proposed by Gu et al. in 2007. Their approach is based on IDS dialog correlation techniques: It deploys three separate network monitors at the network perimeter, each detecting a specific stage of bot infection. By correlating these events, BotHunter can reconstruct the traffic dialog between the infected machine and the outside Internet. From this dialog, the engine determines whether a bot infection has taken place with a high accuracy rate.[30]

Moving beyond the scope of a single network/organization, traffic from centralized botnets can be detected at the ISP level based only on transport layer flow statistics. This approach was developed by Karasaridis et al., and it solves many of the problems of packet-level inspection. It is passive, highly scalable, and only uses flow summary data (limiting privacy issues). Additionally, it can determine the size of a botnet without joining and can even detect botnets using encrypted C & C. The approach exploits the underlying principle of centralized botnets: Each bot has to contact the C&C server, producing detectable patterns in network traffic flows.[31]

Beyond the ISP level, a heuristic method for Internet-wide bot detection was proposed by Ramachandran et al. in 2006. In this scheme, query patterns of DNS blackhole lists (DNSBLs) are used to create a list of possible bot-infected IP addresses. It relies on the fact that botmasters need to periodically check whether their spam-sending bots have been added to a DNSBL and have therefore become useless. The query patterns of botmasters to a DNSBL are very different from those of legitimate mail servers, allowing detection.[32] One major limitation is that this approach focuses mainly on the sending of spam. It would most likely not detect bots engaged in other illegal activities, such as DDoS attacks or click fraud, since these do not require DNSBL lookups.

Detecting and Neutralizing the C&C Servers

Though detecting C&C traffic and eliminating all bots on a given local network is a step in the right direction, it still doesn't allow the takedown of an entire botnet at once. To achieve this goal in a centralized botnet, access to the C&C servers must be removed. This approach assumes that the C&C servers consist of only a few hosts that are accessed directly. If hundreds or thousands of hosts are used in a fast-flux proxy configuration, it becomes extremely challenging to locate and neutralize the true C&C servers.

In work similar to BotHunter, researchers Gu et al. developed BotSniffer in 2008. This approach represents several improvements, notably that BotSniffer can handle encrypted traffic, since it no longer relies only on content inspection to correlate messages. A major advantage of this approach is that it requires no advance knowledge of the bot's signature or the identity of C&C servers. By analyzing network traces, BotSniffer detects the spatial-temporal correlation among C&C traffic belonging to the same botnet. It can therefore detect both the bot members and the C&C server(s) with a low false positive rate.[33]

Most of the approaches mentioned under "Detecting C&C Traffic" can also be used to detect the C&C servers, with the exception of the DNSBL approach.[33] However, their focus is mainly on detection and removal of individual bots. None of these approaches mentions targeting the C&C servers to eliminate an entire botnet.

One of the few projects that has explored the feasibility of C&C server takedown is the work of Freiling et al. in 2005.[34] Although their focus is on DDoS prevention, they describe the method that is generally used in the wild to remove C&C servers when they are detected. First, the bot binary is either reverse-engineered or run in

a sandbox to observe its behavior, specifically the hostnames of the C&C servers. Using this information, the proper dynamic DNS providers can be notified to remove the DNS entries for the C&C servers, preventing any bots from contacting them and thus severing contact between the botmaster and his botnet. Dagon et al. used a similar approach in 2006 to obtain experiment data for modeling botnet propagation, redirecting the victim's connections from the true C&C server to their sinkhole host.[35] Even though effective, the manual analysis and contact with the DNS operator is a slow process. It can take up to several days until all C&C servers are located and neutralized. However, this process is essentially the best available approach for shutting down entire botnets in the wild. As we mentioned, this technique becomes much harder when fast-flux proxies are used to conceal the real C&C servers or a P2P topology is in place.

Attacking Encrypted C&C Channels

Although some of the approaches can detect encrypted C&C traffic, the presence of encryption makes botnet research and analysis much harder. The first step in dealing with these advanced botnets is to penetrate the encryption that protects the C&C channels.

A popular approach for adding encryption to an existing protocol is to run it on top of SSL/TLS; to secure HTTP traffic, ecommerce Web sites run HTTP over SSL/TLS, known as HTTPS. Many encryption schemes that support key exchange (including SSL/TLS) are susceptible to man-in-the-middle (MITM) attacks, whereby a third party can impersonate the other two parties to each other. Such an attack is possible only when no authentication takes place prior to the key exchange, but this is a surprisingly common occurrence due to poor configuration.

The premise of an MITM attack is that the client does not verify that it's talking to the real server, and vice versa. When the MITM receives a connection from the client, it immediately creates a separate connection to the server (under a different encryption key) and passes on the client's request. When the server responds, the MITM decrypts the response, logs and possibly alters the content, then passes it on to the client reencrypted with the proper key. Neither the client nor the server notices that anything is wrong because they are communicating with each other over an encrypted connection, as expected. The important difference is that unknown to either party, the traffic is being decrypted and reencrypted by the MITM in transit, allowing him to observe and alter the traffic.

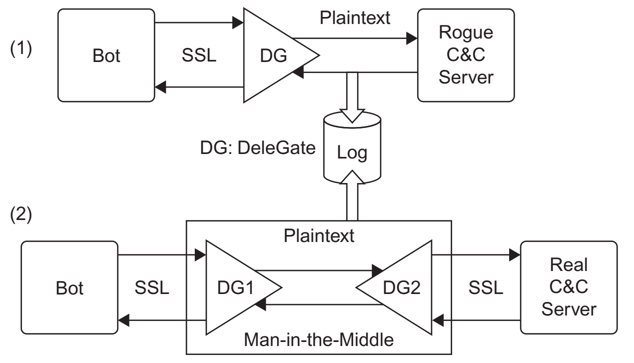

FIGURE 12.2 Setups for man-in-the-middle attacks on encrypted C&C channels.

In the context of bots, two main attacks on encrypted C&C channels are possible: (1) "gray-box" analysis, whereby the bot communicates with a local machine impersonating the C&C server, and (2) a full MITM attack, in which the bot communicates with the true C&C server. Figure 12.2 shows a possible setup for both attacks, using the DeleGate proxy[36] for the conversion to and from SSL/TLS.

The first attack is valuable to determine the authentication information required to join the live botnet: the address of the C&C server, the IRC channel name (if applicable), plus any required passwords. However, it does not allow the observer to see the interaction with the larger botnet, specifically the botmaster. The second attack reveals the full interaction with the botnet, including all botmaster commands, the botmaster password used to control the bots, and possibly the IP addresses of other bot members (depending on the configuration of the C&C server). Figures 12.3–12.5 show the screenshots of the full MITM attack on a copy of Agobot configured to connect to its C&C server via SSL/TLS. Specifically, Figure 12.3 shows the botmaster's IRC window, with his commands and the bot's responses. Figure 12.4 shows the encrypted SSL/TLS trace, and Figure 12.5 shows the decrypted plaintext that was observed at the DeleGate proxy. The botmaster password *botmasterPASS* is clearly visible, along with the required username, *botmaster*.

Armed with the botmaster username and password, the observer could literally take over the botnet. He could log in as the botmaster, then issue a command such as Agobot's .bot.remove, causing all bots to disconnect from the botnet and permanently remove themselves from the infected computers. Unfortunately, there are legal issues with this approach because it constitutes unauthorized access to all the botnet computers, despite the fact that it is in fact a benign command to remove the bot software.

Locating and Identifying the Botmaster

Shutting down an entire botnet at once is a significant achievement, especially when the botnet numbers in the tens of thousands of members. However, there is nothing stopping the botmaster from simply deploying new bots to infect the millions of vulnerable hosts on the Internet, creating a new botnet in a matter of hours. In fact, most of the machines belonging to the shutdown botnet are likely to become infected again because the vulnerabilities and any attacker-installed backdoors often remain active, despite the elimination of the C&C servers. Botnet-hunting expert Gadi Evron agrees: "When we disable a command-and-control server, the botnet is immediately recreated on another host. We're not hurting them anymore," he said in a 2006 interview.[37]

The only permanent solution of the botnet problem is to go after the root cause: the botmasters. Unfortunately, most botmasters are very good at concealing their identities and locations, since their livelihood depends on it. Tracking the botmaster to her true physical location is a complex problem that is described in detail in the next part of the chapter. So far, there is no published work that would allow automated botmaster traceback on the Internet, and it remains an open problem.

6. BOTMASTER TRACEBACK

The botnet field is full of challenging problems: obfuscated binaries, encrypted C&C channels, fast-flux proxies protecting central C&C servers, customized communication protocols, and many more (see Figure 12.6). Arguably the most challenging task is locating the botmaster. Most botmasters take precautions on multiple levels to ensure that their connections cannot be traced to their true locations.

The reason for the botmaster's extreme caution is that a successful trace would have disastrous consequences. He could be arrested, his computer equipment could be seized and scrutinized in detail, and he could be sentenced to an extended prison term. Additionally, authorities would likely learn the identities of his associates, either from questioning him or by searching his computers. As a result, he would never again be able to operate in the Internet underground and could even face violent revenge from his former associates when he is released.

In the United States, authorities have recently started to actively pursue botmasters, resulting in several arrests and convictions. In November 2005, 20-year-old Jeanson James Ancheta of California was charged with botnet-related computer offenses.[38] He pleaded guilty in January 2006 and could face up to 25 years in prison.[39] In a similar case, 20-year-old Christopher Maxwell was indicted on federal computer charges. He is accused of using his botnet to attack computers at several universities and a Seattle hospital, where bot infections severely disrupted operations.[26]

In particular, the FBI's Operation Bot Roast has resulted in several high-profile arrests, both in the United States and abroad.[40] The biggest success was the arrest of 18-year-old New Zealand native Owen Thor Walker, who was a member of a large international computer crime ring known as the A-Team. This group is reported to have infected up to 1.3 million computers with bot software and caused about $20 million in economic damage. Despite this success, Walker was only a minor player, and the criminals in control of the A-Team are still at large.[27]

Unfortunately, botmaster arrests are not very common. The cases described here represent only several individuals; thousands of botmasters around the world are still operating with impunity. They use sophisticated techniques to hide their true identities and locations, and they often operate in countries with weak computer crime enforcement. The lack of international coordination, both on the Internet and in law enforcement, makes it hard to trace botmasters and even harder to hold them accountable to the law.[20]

Traceback Challenges

One defining characteristic of the botmaster is that he originates the botnet C&C traffic. Therefore, one way to find the botmaster is to track the botnet C&C traffic. To hide himself, the botmaster wants to disguise his link to the C&C traffic via various traffic-laundering techniques that make tracking C&C traffic more difficult. For example, a botmaster can route his C&C traffic through a number of intermediate hosts, various protocols, and low-latency anonymous networks to make it extremely difficult to trace. To further conceal his activities, a botmaster can also encrypt his traffic to and from the C&C servers. Finally, a botmaster only needs to be online briefly and send small amounts of traffic to interact with his botnet, reducing the chances of live traceback. Figure 12.6 illustrates some of the C&C traffic-laundering techniques a botmaster can use.

Stepping Stones

The intermediate hosts used for traffic laundering are known as *stepping stones*. The attacker sets them up in a chain, leading from the botmaster's true location to the C&C server. Stepping stones can be SSH servers, proxies (such as SOCKS), IRC bouncers (BNCs), virtual private network (VPN) servers, or any number of network redirection services. They usually run on compromised hosts, which are under the attacker's control and lack audit/logging mechanisms to trace traffic. As a result, manual traceback is tedious and time consuming, requiring the cooperation of dozens of organizations whose networks might be involved in the trace.

The major challenge posed by stepping stones is that all routing information from the previous hop (IP headers, TCP headers, and the like) is stripped from the data before it is sent out on a new, separate connection. Only the content of the packet (the application layer data) is preserved, which renders many existing tracing schemes useless. An example of a technique that relies on routing header information is *probabilistic packet marking* (PPM). This approach was introduced by Savage et al. in 2000, embedding tracing information in an unused IP header field.[41] Two years later, Goodrich expanded this approach, introducing "randomize-and-link" for better scalability.[42] Another technique for IP-level traceback is the log/hash-based scheme introduced by Snoeren et al.[43] and enhanced by Li et al.[44] These techniques were very useful in combating the fast-spreading worms of the early 2000s, which did not use stepping stones. However, these approaches do not work when stepping stones are present, since IP header information is lost.

Multiple Protocols

Another effective and efficient method to disguise the botmaster is to launder the botnet C&C traffic across other protocols. Such protocol laundering can be achieved by either *protocol tunneling* or *protocol translation*. For example, a sophisticated botmaster could route its command and control traffic through SSH (or even HTTP) tunnels to reach the command and control center. The botmaster could also use some intermediate host *X* as a stepping stone, use some real-time communication protocols other than IRC between the botmaster host and host *X*, and use IRC between the host *X* and the IRC server. In this case, host *X* performs the protocol translation at the application layer and serves as a conduit of the botnet C&C channel. One protocol that is particularly suitable for laundering the botnet command and control is instant messaging (IM), which supports real-time text-based communication between two or more people.

Low-Latency Anonymous Network

Besides laundering the botnet C&C across stepping stones and different protocols, a sophisticated botmaster could anonymize its C&C traffic by routing it through some low-latency anonymous communication systems. For example, Tor—the second generation of onion routing—uses an overlay network of onion routers to provide anonymous outgoing connections and anonymous hidden services. The botmaster could use Tor as a virtual tunnel to anonymize his TCP-based C&C traffic to the IRC server of the botnet. At the same time, the IRC server of the botnet could utilize Tor's hidden services to anonymize the

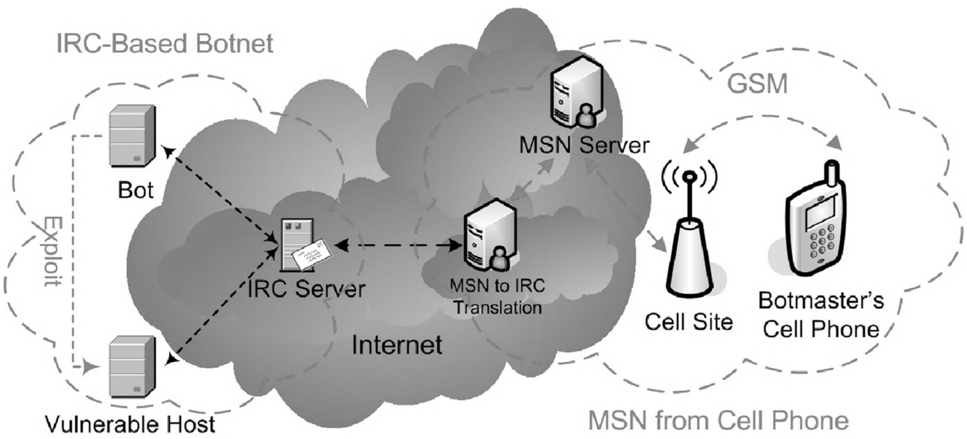

FIGURE 12.7 Using a cell phone to evade Internet-based traceback.

IRC server of the botnet in such a way that its network location is unknown to the bots, and yet it could communicate with all the bots.

Encryption

All or part of the stepping stone chain can be encrypted to protect it against content inspection, which could reveal information about the botnet and botmaster. This can be done using a number of methods, including SSH tunneling, SSL/TLS-enabled BNCs, and IPsec tunneling. Using encryption defeats all content-based tracing approaches, so the tracer must rely on other network flow characteristics, such as packet size or timing, to correlate flows to each other.

Low-Traffic Volume

Since the botmaster only has to connect briefly to issue commands and retrieve results from his botnet, a low volume of traffic flows from any given bot to the botmaster. During a typical session, only a few dozen packets from each bot can be sent to the botmaster. Tracing approaches that rely on analysis of packet size or timing will most likely be ineffective because they typically require a large amount of traffic (several hundred packets) to correlate flows with high statistical confidence. Examples of such tracing approaches[45,46,47] all use timing information to embed a traceable watermark. These approaches can handle stepping stones, encryption, and even low-latency anonymizing network, but they cannot be directly used for botmaster traceback due to the low traffic volume.

Traceback Beyond the Internet

Even if all three technical challenges can be solved and even if all Internet-connected organizations worldwide cooperate to monitor traffic, there are additional traceback challenges beyond the reach of the Internet (see Figure 12.7). Any IP-based traceback method assumes that the true source IP belongs to the computer the attacker is using and that this machine can be physically located. However, in many scenario this is not true—for example, (1) Internet-connected mobile phone networks, (2) open wireless (Wi-Fi) networks, and (3) public computers, such as those at libraries and Internet cafés.

Most modern cell phones support text-messaging services such as Short Message Service (SMS) and many smart phones also have full-featured IM software. As a result, the botmaster can use a mobile device to control her botnet from any location with cell phone reception. To enable her cell phone to communicate with the C&C server, a botmaster needs to use a protocol translation service or a special IRC client for mobile phones. She can run the translation service on a compromised host, an additional stepping stone. For an IRC botnet, such a service would receive the incoming SMS or IM message, then repackage it as an IRC message and send it on to the C&C server (possibly via more stepping stones), as shown in Figure 12.7. To eliminate the need for protocol translation, the botmaster can run a native IRC client on a smart phone with Internet access. Examples of such clients are the Java-based WLIrc[48] and jmIrc[49] open-source projects. In Figure 12.8, a Nokia smartphone is shown

running MSN Messenger, controlling an Agobot zombie via MSN-IRC protocol translation. On the screen, a new bot has just been infected and has joined the IRC channel following the botmaster's .scan.dcom command.

When a botnet is being controlled from a mobile device, even a perfect IP traceback solution would only reach as far as the gateway host that bridges the Internet and the carrier's mobile network. From there, the tracer can ask the carrier to complete the trace and disclose the name and even the current location of the cell phone's owner. However, there are several problems with this approach. First, this part of the trace again requires lots of manual work and the cooperation of yet another organization, introducing further delays and making a real-time trace unlikely. Second, the carrier won't be able to determine the name of the subscriber if he is using a prepaid cell phone. Third, the tracer could obtain an approximate physical location based on cell site triangulation. Even if he can do this in real time, it might not be very useful if the botmaster is in a crowded public place. Short of detaining all people in the area and checking their cell phones, police won't be able to pinpoint the botmaster.

A similar situation arises when the botmaster uses an unsecured Wi-Fi connection. This could either be a public access point or a poorly configured one that is intended to be private. With a strong antenna, the botmaster can be located up to several thousand feet away. In a typical downtown area, such a radius can contain thousands of people and just as many computers. Again, short of searching everyone in the vicinity, the police will be unable to find the botmaster.

Finally, many places provide public Internet access without any logging of the users' identities. Prime examples are public libraries, Internet cafés, and even the business centers at most hotels. In this scenario, a real-time trace would actually find the botmaster, since he would be sitting at the machine in question. However, even if the police are late by only several minutes, there might no longer be any record of who last used the computer. Physical evidence such as fingerprints, hair, and skin cells would be of little use, since many people use these computers each day. Unless a camera system is in place and it captured a clear picture of the suspect on his way to/from the computer, the police again will have no leads.

This part of the chapter illustrated a few common scenarios where even a perfect IP traceback solution would fail to locate the botmaster. Clearly, much work remains on developing automated, integrated traceback solutions that work across various types of networks and protocols.

Finally, let's briefly look at how to prevent botnets. The most important thing to remember is that prevention is an ongoing process. An organization can't just set everything up and expect to be protected forever. Also, it's important to remember that unless an organization employs common sense and prudent Internet communication habits, they're courting disaster.

7. PREVENTING BOTNETS

One of the most common problems during botnet incident handling (preventing botnets), particularly in widespread incidents, is poor communication and coordination. Anyone involved in an incident, including users, can inadvertently cause additional problems because of a limited view or understanding of the situation. To improve communication and coordination, an organization should designate in advance a few individuals or a small team to be responsible for coordinating the organization's responses to botnet incidents. The coordinator's primary goal is to maintain situational awareness by gathering all pertinent information, making decisions that are in the best interests of the organization, and communicating pertinent information and decisions to all relevant parties within the organization in a timely manner. For botnet incidents, the relevant parties often include end users, who might be given instructions on how to avoid infecting their systems, how to recognize the signs of an infection, and what to do if a system appears to be infected. The coordinator also needs to provide technical guidance and instructions to all staff assisting with containment, eradication, and recovery efforts, as well as giving management regular

updates on the status of the response and the current and likely future impact of the incident.

Because widespread botnet incidents often disrupt email services, internal Web sites, Voice over IP, and other forms of communication, organizations should have several communication mechanisms established, so that good communication and coordination among incident handlers, technical staff, management, and users can be sustained during adverse events. Possible communication methods include the organization's phone system, cell phones, pagers, email, fax, and paper. Even under good conditions, it is often effective to use different communication methods for different audiences (for example, communicating to users through email, but using a standard conference call phone number for discussions among key technical personnel). Management updates could occur in person, through conference calls, or through a voice mailbox greeting that is updated regularly with the incident status and other helpful information.

Organizations should also establish a point of contact for answering questions about the legitimacy of botnet alerts. Many organizations use the IT help desk as the initial point of contact and give help desk agents access to sources of information on real botnet threats and virus hoaxes, so that they can quickly determine the legitimacy of an alert and provide users with guidance on what to do. Organizations should caution users not to forward botnet alerts to others without first confirming that the alerts are legitimate.

Organizations should also ensure that they have the necessary tools (hardware and software) and resources to assist in handling botnet incidents. Examples of tools include packet sniffers and protocol analyzers. Additional tools include antivirus software, spyware detection and removal utilities, and host-based IPS software that incident handlers should be able to use. Incident handling teams may choose to build hash sets of known good operating system and application files, so that they are better prepared to determine how the botnet has altered a system. Examples of resources include lists of contact and on-call information, commonly used port numbers, and known critical assets.

So, if an organization practices careful Internet communication habits and follows the key tools and resources for botnet incident handlers tips described in the checklist that follows, the chances of the computer remaining secure are very good (see checklist: An Agenda for Action for Preventing Botnet Activities).

8. SUMMARY

Botnets are one of the biggest threats to the Internet today, and they are linked to most forms of Internet crime. Most spam, DDoS attacks, spyware, click fraud, and other attacks originate from botnets and the shadowy organizations behind them. Running a botnet is immensely profitable, as several recent high-profile arrests have shown. Currently, many botnets still rely on a centralized IRC C&C structure, but more and more botmasters are using P2P protocols to provide resilience and avoid a single point of failure. A recent large-scale example of a P2P botnet is the Storm Worm, widely covered in the media.

A number of botnet countermeasures exist, but most are focused on bot detection and removal at the host and network level. Some approaches exist for Internet-wide detection and disruption of entire botnets, but we still lack effective techniques for combating the root of the problem: the botmasters who conceal their identities and locations behind chains of stepping-stone proxies.

The three biggest challenges in botmaster traceback are stepping stones, encryption, and the low traffic volume. Even if these problems can be solved with a technical solution, the trace must be able to continue beyond the reach of the Internet. Mobile phone networks, open wireless access points, and public computers all provide an additional layer of anonymity for the botmasters.

Short of a perfect solution, even a partial traceback technique could serve as a very effective deterrent for botmasters. With each botmaster that is located and arrested, many botnets will be eliminated at once. Additionally, other botmasters could decide that the risks outweigh the benefits when they see more and more of their colleagues getting caught. Currently, the economic equation is very simple: Botnets can generate large profits with relatively low risk of getting caught. A botmaster traceback solution, even if imperfect, would drastically change this equation and convince more botmasters that it simply is not worth the risk of spending the next 10−20 years in prison.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? A botnet is a collection of compromised Internet computers being controlled remotely by attackers for malicious and legal purposes.
2. True or False? The person controlling a botnet is known as the botmaster or bot-herder.
3. True or False? Centralized botnets use a double entity (a host or a small collection of hosts) to manage all bot members.
4. True or False? The attacker exploits a vulnerability in a running service to automatically gain access and install his software without any user interaction.
5. True or False? After infection, the bot starts up for the first time and attempts to contact its C&C server(s) in a process known as waiting.

An Agenda for Action for Preventing Botnet Activities

In order to provide a timely, comprehensive, relevant, and accurate Internet communication security strategy, the following set of preventative botnet activities must be adhered to (check all tasks completed):

Botnet Incident Handler Communications and Facilities

_____1. **Contact information: This includes** phone numbers and email addresses for team members and others within and outside the organization (primary and backup contacts), who may have helpful information, such as antivirus vendors and other incident response teams.

_____2. **On-call information is used** for other teams within the organization, including escalation information.

_____3. **Pagers or cell phones that are** to be carried by team members for off-hour support, onsite communications.

_____4. **Alternate Internet access method which is used** for finding information about new threats, downloading patches and updates, and reaching other Internet-based resources when Internet access is lost during a severe botnet incident.

_____5. **War room is used** for central communication and coordination; if a permanent war room is not necessary, the team should create a procedure for procuring a temporary war room when needed.

Botnet Incident Analysis Hardware and Software

_____6. **Laptops**, which provide easily portable workstations for activities such as analyzing data and sniffing packets.

_____7. **Spare workstations, servers, and networking equipment**, which may be used for trying out botnets in an isolated environment. If the team cannot justify the expense of additional equipment, perhaps equipment in an existing test lab could be used, or a virtual lab could be established using OS emulation software.

_____8. **Blank media**, such as CDs and flash drives, for storing and transporting botnet samples and other files as needed

_____9. **Packet sniffers and protocol analyzers that are used** to capture and analyze network traffic that may contain botnet activity.

_____10. **Up-to-date, trusted versions of OS executables and analysis utilities, which are** stored on flash drives or CDs, to be used to examine systems for signs of botnet infection (antivirus software, spyware detection and removal utilities, system administration tools, forensics utilities).

Botnet Incident Analysis Resources

_____11. **Port lists, that include** commonly used ports and known Trojan horse and backdoor ports.

_____12. **Documentation** for OSs, applications, protocols, and antivirus and intrusion detection signatures.

_____13. **Network diagrams and lists of critical assets**, such as Web, email, and File Transfer Protocol (FTP) servers.

_____14. **Baselines** of expected network, system and application activity.

Botnet Incident Mitigation Software

_____15. **Media**, which includes OS boot disks and CDs, flash drives, OS media, storage media. and application media.

_____16. **Security patches** from OS and application vendors.

_____17. **Disk imaging software and backup images** of OS, applications, and data stored on secondary media.

Multiple Choice

1. A collection of compromised Internet computers being controlled remotely by attackers for malicious and illegal purposes is known as:
A. malware.
B. spyware.
C. botmaster.
D. botnet.
E. bot-herder.

2. The botmaster develops his or her bot software, often reusing existing code and adding custom features. This is known as:
A. infection.
B. rallying.
C. creation.
D. waiting.
E. executing.

3. Once a victim machine becomes infected with a bot, it is known as a:
A. vampire.
B. werewolf.
C. chost.
D. succubus.
E. zombie.

4. After infection, the bot starts up for the first time and attempts to contact its C&C server(s) in a process known as:
A. infection.
B. creation.
C. rallying.
D. waiting.
E. executing.

5. Having joined the C&C network, the bot waits for commands from the botmaster. This is known as:
A. infection.

B. creation.
C. rallying.
D. executing.
E. waiting.

EXERCISE

Problem

On a Wednesday morning, a new worm is released on the Internet. The worm exploits a Microsoft Windows vulnerability that was publicly announced three weeks before, at which time patches were released. The worm spreads itself through two methods: emailing itself to all addresses that it can locate on an infected host; and identifying and sending itself to hosts with open Windows shares. The worm is designed to generate a different attachment name for each copy that it mails; each attachment has a randomly generated file name that uses one of over a dozen file extensions. The worm also chooses from more than 200 email subjects and a similar number of email bodies. When the worm infects a host, it gains administrative rights and attempts to download a distributed denial-of-service (DDoS) agent from different Internet Protocol (IP) addresses using File Transfer Protocol (FTP). The number of IP addresses providing the agent is unknown. Although the antivirus vendors quickly post warnings about the worm, it spreads very rapidly, before any of the vendors have released signatures. The organization has already incurred widespread infections before antivirus signatures become available four hours after the worm started to spread. What questions should the botnet incident response team be asking?

Hands-On Projects

Project

On a Monday night, one of the organization's network intrusion detection sensors alerts on a suspected outbound DDoS activity involving a high volume of Internet Control Message Protocol (ICMP) pings. The intrusion analyst reviews the alerts; although the analyst cannot confirm that the alerts are accurate, they do not match any known false positives. The analyst contacts the botnet incident response team so that it can investigate the activity further. Because the DDoS activity uses spoofed source IP addresses, it takes considerable time and effort to determine which host or hosts within the organization are producing it; meanwhile, the DDoS activity continues. The investigation shows that eight servers appear to be generating the DDoS traffic. Initial analysis of the servers shows that each contains signs of a DDoS rootkit. What questions should the botnet incident response team be asking?

Case Projects

Problem

On a Saturday afternoon, several users contact the help desk to report strange popup windows and toolbars in their Web browsers. The users' descriptions of the behavior are similar, so the help desk agents believe that the users' systems have been affected by the same thing and that the most likely cause is Web-based malicious mobile code. What questions should the botnet incident response team be asking?

Optional Team Case Project

Problem

Shortly after an organization adopts a new instant messaging platform, its users are hit with a widespread botnet attack that propagates itself through the use of instant messaging. Based on the initial reports from security administrators, the attack appears to be caused by a worm. However, subsequent reports indicate that the attacks also involve Web servers and Web clients. The instant messaging and Web-based attacks appear to be related to the worm because they display the same message to users. What questions should the botnet incident response team be asking?

Chapter 13

Intranet Security

Bill Mansoor
Information Systems Audit and Control Association (ISACA)

Headline dramas like the ones shown in the accompanying sidebar (Intranet Security as News in the Media) (in the mainstream media) are embarrassing nightmares to top brass in any large corporation. These events have a lasting impact on a company's bottom line because the company's reputation and customer trust take a direct hit. Once events like these occur, customers and current and potential investors never look at the company in the same trusting light again, regardless of remediation measures. The smart thing, then, is to avoid the limelight. The onus of preventing such embarrassing security gaffes falls squarely on the shoulders of the IT security chiefs (Chief Information Security Officer and security officers), who are sometimes hobbled by unclear mandates from government regulators and lack of sufficient budgeting to tackle the mandates.

- Intranet Security as News in the Media
- "State Department Contract Employees Fired, Another Disciplined for Looking at Passport File"[1]
- "Laptop stolen with a million customer data records "[2]
- "eBayed VPN kit hands over access to council network "[3]
- "(Employee) caught selling personal and medical information about . . . FBI agent to a confidential source . . . for $500"[4]
- "Data thieves gain access to TJX through unsecured wireless access point"[5]

However, federal governments across the world are not taking breaches of personal data lightly (see sidebar, TJX: Data Breach with 45 Million Data Records Stolen). In view of a massive plague of publicized data thefts in the past decade, recent mandates such as the Health Insurance Portability and Accountability Act (HIPAA), Sarbanes-Oxley, and the Payment Card Industry-Data Security Standard (PCI-DSS) Act within the United States now have teeth. These laws even spell out stiff fines and personal jail sentences for CEOs who neglect data breach issues.

TJX: Data Breach with 45 Million Data Records Stolen

The largest-scale data breach in history occurred in early 2007 at TJX, the parent company for the TJ Maxx, Marshalls, and HomeGoods retail chains.

In the largest identity-theft case ever investigated by the U.S. Department of Justice, 11 people were convicted of wire fraud. The primary suspect was found to perpetrate the intrusion by wardriving and taking advantage of an unsecured Wi-Fi access point to get in and set up a "sniffer" software instance to capture credit-card information from a database.[12]

Although the intrusion was earlier believed to have taken place from May 2006 to January 2007, TJX later found that it took place as early as July 2005. The data compromised included portions of credit- and debit-card transactions for approximately 45 million customers.[6]

As seen in the TJX case, intranet data breaches can be a serious issue, impacting a company's goodwill in the open marketplace as well as spawning class-action lawsuits.[7] Gone are the days when intranet security was a superficial exercise; security inside the firewall was all

but nonexistent. There was a feeling of implicit trust in the internal user. After all, if you hired that person, training him for years, how could you not trust him?

In the new millennium, the Internet has come of age, and so have its users. The last largely computer-agnostic generation has exited the user scene; their occupational shoes have been filled with the X and Y generations. Many of these young people have grown up with the Internet, often familiar with it since elementary school. It is not uncommon today to find young college students who started their programming interests in the fifth or sixth grade.

With such a level of computer expertise in users, the game of intranet security has changed (see sidebar: Network Breach Readiness: Many Are Still Complacent). Resourceful as ever, these new users have gotten used to the idea of being hyperconnected to the Internet using mobile technology such as personal digital assistants (PDAs), smartphones, and firewalled barriers. For a corporate intranet that uses older ideas of using access control as the cornerstone of data security, such mobile access to the Internet at work needs careful analysis and control. The idea of building a virtual moat around your well-constructed castle (investing in a firewall and hoping to call it an intranet) is gone. Hyperconnected "knowledge workers" with laptops, PDAs, and USB keys that have whole operating systems built in have made sure of it.

Network Breach Readiness: Many are Still Complacent

The level of readiness for breaches among IT shops across the country is still far from optimal. The Ponemon Institute, a security think tank, surveyed some industry personnel and came up with some startling revelations. Hopefully, these statistics will change in the future:

- Eighty-five percent of industry respondents reported that they had experienced a data breach.
- Of those responding, 43 percent had no incident response plan in place, and 82 percent did not consult legal counsel before responding to the incident.
- Following a breach, 46 percent of respondents still had not implemented encryption on portable devices (laptops, PDAs) with company data stored on them.[8]

If we could reuse the familiar vehicle ad tagline of the 1980s, we would say that the new intranet is not "your father's intranet anymore." The intranet as just a simple place to share files and to list a few policies and procedures has ceased to be. The types of changes can be summed up in the following list of features, which shows that the intranet has become a combined portal as well as a public dashboard. Some of the features can include:

- A searchable corporate personnel directory of phone numbers by department. Often the list is searchable only if the exact name is known.
- Expanded activity guides and a corporate calendar with links for various company divisions.
- Several Really Simple Syndication (RSS) feeds for news according to divisions such as IT, HR, Finance, Accounting, and Purchasing.
- Company blogs (weblogs) by top brass that talk about the current direction for the company in reaction to recent events, a sort of "mission statement of the month."
- A search engine for searching company information, often helped by a search appliance from Google. Microsoft also has its own search software on offer that targets corporate intranets.
- One or several "wiki" repositories for company intellectual property, some of it of a mission-critical nature. Usually granular permissions are applied for access here. One example could be court documents for a legal firm with rigorous security access applied.
- A section describing company financials and other mission-critical indicators. This is often a separate Web page linked to the main intranet page.
- A "live" section with IT alerts regarding specific downtimes, outages, and other critical time-sensitive company notifications. Often embedded within the portal, this is displayed in a "ticker-tape" fashion or like an RSS-type dynamic display.

Of course, this list is not exhaustive; some intranets have other unique features not listed here. In any case, intranets these days do a lot more than simply list corporate phone numbers.

Recently, knowledge management systems have presented another challenge to intranet security postures. Companies that count knowledge as a prime protected asset (virtually all companies these days) have started deploying "mashable" applications that combine social networking (such as Facebook and LinkedIn), texting, and microblogging (such as Twitter) features to encourage employees to "wikify" their knowledge and information within intranets. One of the bigger vendors in this space, Socialtext, has introduced a mashable wiki app that operates like a corporate dashboard for intranets.[9,10]

9. James Mowery, "Socialtext Melds Media and Collaboration," cmswire.com, October 8, 2008, www.cmswire.com/cms/enterprise-20/socialtext-melds-media-and-collaboration-003270.php.

10. Rob Hof, "Socialtext 3.0: Will Wikis Finally Find Their Place in Business?" Businessweek.com magazine, September 30, 2008, www.business-week.com/the_thread/techbeat/archives/2008/09/socialtext_30_i.html.

Socialtext has individual widgets, one of which, "Socialtext signals," is a microblogging engine. In the corporate context, microblogging entails sending short SMS messages to apprise colleagues of recent developments in the daily routine. Examples could be short messages on progress on any major project milestone—for example, joining up major airplane assemblies or getting Food and Drug Administration (FDA) testing approval for a special experimental drug.

These emerging scenarios present special challenges to security personnel guarding the borders of an intranet. The border as it once existed has ceased to be. One cannot block stored knowledge from leaving the intranet when a majority of corporate mobile users are accessing intranet wikis from anywhere using inexpensive mini-notebooks that are given away with cell phone contracts.[11]

If we consider the impact of national and international privacy mandates on these situations, the situation is compounded further for C-level executives in multinational companies who have to come up with responses to privacy mandates in each country in which the company does business. The privacy mandates regarding private customer data have always been more stringent in Europe than in North America, which is a consideration for doing business in Europe.

It is hard enough to block entertainment-related Flash video traffic from time-wasting Internet abuse without blocking a video of last week's corporate meeting at headquarters. Only letting in traffic on an exception basis becomes untenable or impractical because of a high level of personnel involvement needed for every ongoing security change. Simply blocking YouTube.com or Vimeo.com is not sufficient. Video, which has myriad legitimate work uses nowadays, is hosted on all sorts of content-serving (caching and streaming) sites worldwide, which makes it well near impossible to block using Web filters. The evolution of the Internet Content Adaptation Protocol (ICAP), which standardizes Web site categories for content-filtering purposes, is under way. However, ICAP still does not solve the problem of the dissolving networking "periphery."[12]

Guarding movable and dynamic data—which may be moving in and out of the perimeter without notice, flouting every possible mandate—is a key feature of today's intranet. The dynamic nature of data has rendered the traditional confidentiality, integrity, and availability (CIA) architecture somewhat less relevant. The changing nature of data security necessitates some specialized security considerations:

- Intranet security policies and procedures (P&Ps) are the first step toward a legal regulatory framework. The P&Ps needed on any of the security controls listed below should be compliant with federal and state mandates (such as HIPAA, Sarbanes-Oxley, the European Directive 95/46/EC on the protection of personal data, and PCI-DSS, among others). These P&Ps have to be signed off by top management and placed on the intranet for review by employees. There should be sufficient teeth in all procedural sections to enforce the policy, explicitly spelling out sanctions and other consequences of noncompliance, leading up to discharge.
- To be factual, none of these government mandates spell out details on implementing any security controls. That is the vague nature of federal and international mandates. Interpretation of the security controls is better left after the fact to an entity such as the National Institute of Standards and Technology (NIST) in the United States or the Geneva-based International Organization for Standardization (ISO). These organizations have extensive research and publication guidance for any specific security initiative. Most of NIST's documents are offered as free downloads from its Web site.[13] ISO security standards such as 27002 ~ 27005 are also available for a nominal fee from the ISO site.

Policies and procedures, once finalized, need to be automated as much as possible (one example is mandatory password changes every three months). Automating policy compliance takes the error-prone human factor out of the equation (see sidebar: Access Control in the Era of Social Networking). Numerous software tools are available to help accomplish security policy automation.

Access Control in the Era of Social Networking

In an age in which younger users have grown up with social networking sites as part of their digital lives, corporate intranet sites are finding it increasingly difficult to block them from using these sites at work. Depending on the company, some are embracing social networking as part of their corporate culture; others, especially government entities, are actively blocking these sites. Detractors mention as concerns wasted bandwidth, lost productivity, and the possibility of infections with spyware and worms.

However, blocking these sites can be difficult because most social networking and video sites such as Vimeo and YouTube can use port 80 to vector Flash videos into an

intranet—which is wide open for HTTP access. Flash videos have the potential to provide a convenient Trojan horse for malware to get into the intranet.

To block social networking sites, one needs to block either the Social Networking category or the specific URLs (such as YouTube.com) for these sites in the Web-filtering proxy appliance. Flash videos are rarely downloaded from YouTube itself. More often a redirected caching site is used to send in the video. The caching sites also need to be blocked; this is categorized under Content Servers.

1. SMARTPHONES AND TABLETS IN THE INTRANET

The proliferation of mobile devices for personal and business usage has gained an unprecedented momentum, which only reminds one of the proliferation of personal computers at the start of the 1980s. Back then the rapid proliferation of PCs was rooted in the wide availability of common PC software and productivity packages such as Excel or Borland. Helping with kids' homework and spreadsheets at home was part of the wide appeal.

A large part of the PC revolution was also rooted in the change in interactivity patterns. Interaction using GUIs and mice had made PCs widely popular compared to the DOS character screen. The consumer PC revolution did not really take off until Windows PCs and Mac Classics brought along mice starting in the early 1990s. It was a quantum leap for ordinary people unfamiliar with DOS commands.

Today, which some now call the post-PC era,[14] the interaction between people and computers has again evolved. The finger (touch) has again replaced keyboards and mice as an input device in smartphones and tablets—which invariably use a mobile-oriented OS like Android or iOS as opposed to MAC OS, Linux, or Windows. Android and iOS were built from the ground up with the "touch interface" in mind.

This marks a sea-change.[15] By the next couple of years, most smartphones will end up with the computing power of a full-size PC that is only five years older. These powerful smartphones and portable tablets (such as iPads and android devices) enabled with multimedia and gaming capabilities are starting to converge toward becoming one and the same device. The increasing speed and functionality for the price ("bang for the buck") will only gather a more rapid pace as user demand becomes more intense. The success of smartphones and tablet devices over traditional full-size laptops stems from two primary reasons:

1. **The functionality and ease of use of using "voice," "gesture," and "touch" interfaces.** As opposed to the use of mice and keyboards, voice-enabled, touch, and gesture-based interfaces used in mobile devices offer a degree of ease unseen in traditional laptops.
2. **The availability of customized apps (applications).** Given the number of specialized apps found in the Apple App Store (and Android's equivalent "market"), they offer increased versatility for these new mobile devices compared to traditional laptops. In Apple's case, the closed ecosystem of apps (securely allowed only after testing for security) decreases the possibility of hacking iPads using uncertified apps.

In the recent iPhone 4s, the use of "Siri" as a speech-aware app only portends the increasing ease of usage for this class of device.[16] Using Siri, the iPhone can be issued voice commands to set appointments, to read back messages, and to notify people if one is going to be late—among a myriad other things—all without touching any keypad. In the recently introduced android version 4.0 or higher, face recognition authentication using the on-board camera is also an ease-of-use feature. There are bugs in these applications of course, but they indisputably point toward a pattern of interactivity change compared to a traditional laptop. There are a few other trends to watch in the integration of mobile devices in the enterprise:

1. Mobile devices let today's employees stretch work far beyond traditional work hours. Because of rich interactivity and ease of use, these devices blur the boundary between work and play. Companies benefit from this employee availability at non-traditional work hours. The very concept of being at work has changed compared to even 10 years ago.
2. The iteration life cycles of mobile devices are now more rapid. Unlike laptops that had life cycles of almost three years, new version of the iPad comes out almost every year with evolutionary changes. This makes it less and less feasible for IT to set standardization for mobile devices or even pay for them. IT is left in most cases with supporting these devices. IT can, however, put in recommendations on which device it is able or unable to support for feasibility reasons.
3. Because of these cost reasons, it is no longer feasible for most IT departments to dictate the brand or platform of mobile device employees use to access the

corporate network. It is often a BYOD (Bring Your Own Device) situation. As long as specialized software can be used to partition the personally owned mobile device for storing company data safely (which cannot be breached), this approach is feasible.

4. The mobile device that seems to be numerically most ready for the enterprise is the same one that has been the most successful commercially, the Apple iPad. Already in its third iteration in 2012 since the first one came out in 2010, the iPad 3 with its security and VPN features seems to be ready to be managed by most Mobile Device Management (MDM) packages. It has been adopted extensively by executives and sales staff at larger corporate entities.[17] It is also starting to be adopted by state and local government to expedite certain e-government initiatives.[18]
5. Compared to the Apple iPhone, however, the Android smartphones generally have had better adoption rates. Blackberry adoption, however, is on the wane.[19] Smartphones will need to have more specially designed Web pages to cope with interactivity on a smaller screen.
6. According to a major vendor in the Mobile Device Management space ("Good Technology") the financial services sector saw the highest level of iPad (iOS) activation, accounting for 46 percent for the third quarter in 2011—which tripled the amount of activation in any other industry (see Figure 13.1). [20]

When it comes to mobile devices (see sidebar: The Commoditization of Mobile Devices and Impact upon Businesses and Society) and smartphones, one can reasonably surmise that the act of balancing security versus business considerations has clearly tilted toward the latter. The age of mobile devices is here, and IT has to adapt security measures to conform to it. The common IT security concept of protecting the host may have to convert to protecting the network from itinerant hosts.

The Commoditization of Mobile Devices and Impact upon Businesses and Society

There are quite a few increasingly visible trends that portend the commoditization of mobile devices and their resulting impact on businesses.

1. The millennial generation is more familiar with mobile technology—Due to widespread usage of smartphones and iPhones as communication devices for computing usage (other than simply voice) in the last few years and now iPads which have taken their place, their familiarity with mobile hardware is far higher than previous generations. The technological sophistication of these devices has forced the majority of the current generation of young people to be far more tech savvy than previous generations as they have grown up around this mobile-communication-enabled environment.
2. Mobile devices are eating into the sales of PCs and laptops—The millennial generation is no longer simply content with traditional bulky PCs and laptops as computing devices. Lightweight devices with pared-down mobile OSs and battery-efficient mobile devices with 10-hour lives are quickly approaching the computing power of traditional computers and in addition are far more portable. The demand of lowered cost, immediacy, and ease of usage of mobile devices have caused traditional laptop sales to slow down in favor of tablet and iPad sales.
3. Social media usage by mobile devices—Sites like FaceBook, Twitter, and Flickr encourage collaboration and have given rise to usage of these sites using nothing other than mobile devices, whereas this was not possible previously. Most smartphones (even an increasingly common class of GPS-enabled point-and-shoot cameras) enable upload of images and videos to these sites directly from the device itself using Wi-Fi connections and Wi-Fi-enabled storage media (SD cards). This has engendered a mobile lifestyle for this generation that sites such as FaceBook, Twitter, and Flickr are only too happy to cater to. Employees using social media represent new challenges to businesses because protection of business data (enforced by privacy-related federal and state regulations and mandates) has become imperative. Business data has to be separated and protected from personal use of public social media, if they have to exist on the same mobile device. Several vendors already offer products that enable this separation. In industry parlance this area of IT is known as Mobile Device Management.
4. The mobile hardware industry has matured—Margins have been pared to the bone. Mobile devices have become a buyers' market. Because of wider appeal, it is no longer just the tech savvy (opinion leaders and early adopters) who determine the success of a mobile product. It will be the wider swath of nontechie users looking for attractive devices with a standardized set of often-used functions that will determine the success of a product. This will sooner than later force manufacturers to compete on price rather than product innovation. This downward pressure on price will also make it cost-effective for businesses to adopt these mobile devices within their corporate IT infrastructure. Amazon's Kindle and Barnes &Noble's Nook are both nimbly designed and priced at around a $200 price-point compared to the $500 iPad. They have begun to steal some market share from full-featured tablets like the iPad but of course enterprise adoption for the cheaper devices remains to be sorted out.
5. Users expect the "cloud" to be personal—Users in their personal lives have become used to customizing their Internet digital persona by being offered limitless choices in doing so. In their usage of the business cloud," they expect the same level of customization. This customization can be easily built into the backend using the likes of Active Directory and collaboration tools such as Microsoft's SharePoint once a user authenticates through the VPN. Customization can be built upon access permissions in a granular manner per user while tracking their access to company information assets. This accumulated data trend can be used later to refine ease of use for remote users using the company portal.

In 2011, Apple shipped 172 million portable computing devices including iPads, iPods, and iPhones. Among these were 55 million iPads. The sales of mostly android tablets by other manufacturers are also increasing at a rapid pace. By the end of the first decade of the new millennium, it has become clear that sales of iPads and tablets are making serious dents in the sale of traditional PCs—indicating a shift in consumer preference toward a rapid commoditization of computing. Figure 13.2 from the Forrester Research consumer PC and Tablet forecast helps illustrate this phenomenon.[21]

21. Zack Whittaker, "One Billion Smartphones by 2016, Says Forrester," February 13, 2012, http://www.zdnet.com/blog/btl/one-billion-smartphones-by-2016-says-forrester/69279.

Several reasons can be attributed to this shift. The millennial generation was already reinventing the idea of how business is conducted and where. Because of increased demands on employee productivity, business had to be conducted in real time at the employee's location (home, hotel, airport) and not just at the traditional workplace. With gas prices hovering in the United States around $5.00 a gallon (essentially a doubling of prices over the first half-decade of the millennium), traditional 9-to-5 work hours with long commutes are no longer practical. iPads and tablets therefore had become *de rigueur* for not only field employees but also workers at headquarters. Instead of imposing rigid 9-to-5 attendance on employees, progressive companies had to let employees be flexible in meeting

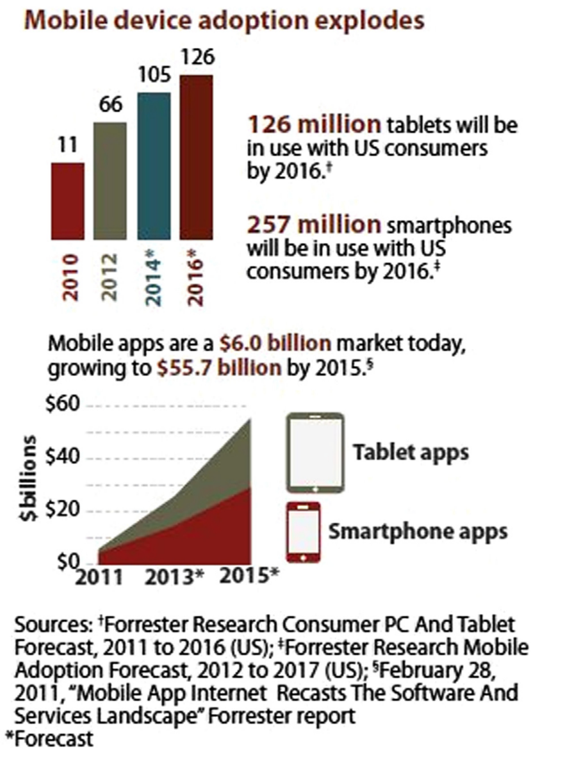

FIGURE 13.2 Mobile device adaptation. Source*:* *http://i.zdnet.com/blogs/screen-shot-2012-02-13-at-173416.png*.

Being Secure in the Post-PC Era

The post-PC era began with the advent of tablets such as iPads as enterprise mobile computing devices. Secure use of tablets in the enterprise presupposes a number of conditionalities:

1. **Backend enterprise network infrastructure support has to be ready** and has to be strong to handle mobile devices interacting with SSL VPNs. Specifically, enterprises need to consider each device platform and their unique issues and idiosyncrasies in trying to connect using an SSL VPN. SSL (or Web) VPNs are preferred because IPSec and L2TP VPNs were not known to be easy to implement on mobile devices (especially Android tablets) as SSL VPNs. PPTP VPNs are dated and not known to have sufficient encryption and security compared to SSL VPNs.
2. **Testing of remote access scenarios such as VPNs is key.** Client Apps for each supported platform (iOS, Android, Windows Phone) against the existing or proposed VPN appliance will need to be thoroughly tested.
3. **This is fundamentally a new paradigm for delivering applications** (email, dashboards, databases) to users. Starting with a practical and functional client App from ground zero will be a better philosophy than sticking to existing GUI ideas or concepts. Instead of pretty but nonfunctional interfaces, spare but well-tested and robust mobile interfaces will afford users time-savings and efficiency to get their job done quicker. Once they are reliably working, additional functions can be slowly added to the app in successive versions.

sales or deliverables on their own deadlines, which improved employee morale and productivity.

Popular devices like the iPad, Samsung Galaxy Android tablet, and many types of smartphones are already capable of accessing company intranets using customized intranet apps. This assures that access to critical company data needed for a sale or demo does not stand in the way of closing an important deal. All this had already been enabled by laptops, but the touchpad-enabled tablet eases this process by using more functional media usage and richer interactivity features.

Ultimately, it will matter less about what device employees use to access the company portal or where they are because their identity will be the deciding factor in what information they will gain access to. Companies will do better in providing customized "private cloud environments" for workers accessible from anywhere. Employees may still use PCs while at the office (see sidebar: Being Secure in the Post-PC Era) and mobile devices while in the field conducting business, but they will increasingly demand the same degree of ease in accessing company data regardless of their location or the means used to access it. The challenge for IT will be in catering to these versatile demands without losing sight of security and protecting privacy.

2. SECURITY CONSIDERATIONS

Quite a few risks need to be resolved when approaching intranet security with regard to mobile devices:

1. **Risk of size and portability—**Mobile devices are prone to loss. An Apple staffer's "loss" of a fourth-generation iPhone to a Gizmodo staffer during a personal outing to a bar is well known. There is no denying that smartphones because of their size are easy theft targets in the wrong place at the wrong time. Loss of a few hundred dollars of hardware, however, is nothing when an invaluable client-list is lost and falls into a competitor's hands. These are nightmare scenarios that keep CIOs up at night.
2. **Risk of access via multiple paradigms—**Mobile devices can access unsafe sites using cellular networks and download malware into storage. The malware in turn can bypass the company firewall to enter the company network to wreak havoc. Old paradigms of security by controlling security using perimeter network access are no longer feasible.
3. **Social media risks—**By definition, mobile devices are designed in such a way that they can easily access

social media sites, which are the new target for malware propagating exploits. Being personal devices, mobile media devices are much more at risk of getting exploits sent to them and being "pw" (so to speak).

These issues can be approached and dealt with by using a solid set of technical as well as administrative controls:

1. **Establish a customized corporate usage policy for mobile devices—**This policy/procedure must be signed by new hires at orientation and by all employees who ask for access to the corporate VPN using mobile devices (even personal ones). This should ideally be in the form of a contract and should be signed by the employee before a portion of the employee's device storage is partitioned for access and storage of corporate data. Normally, there should be yearly training highlighting the do's and dont's of using mobile devices in accessing a corporate VPN. The first thing emphasized in this training should be how to secure company data using passwords and if cost-effective, two-factor authentication using hardware tokens.
2. **Establish a policy for reporting theft or misplacement—**This policy should identify at the very least how quickly one should report thefts of mobile devices containing company data and how quickly remote wipe should be implemented. The policy can optionally detail how the mobile devices feature (app) enabling location of the misplaced stolen device will proceed.
3. **Establish a well-tested SSL VPN for remote access—**Reputed vendors having experience with mobile device VPN clients should be chosen. The quality, functionality, adaptability of usage (and proven reputation) of the VPN clients should be key in determining the choice of the vendor. The advantage of an SSL VPN compared to IPsec or L2TP for mobile usage is well known. The SSL VPNs should be capable of supporting two-factor authentication using hardware tokens. For example, Cisco's "Cisco AnyConnect Secure Mobility Client" and Juniper's "Junos Pulse App" are free app downloads available within the Apple iTunes App store. Other VPN vendors will also have these apps available, and they can be tested to see how smooth and functional the access process is.
4. **Establish inbound and outbound malware scanning—**Inbound scanning should occur for obvious reasons, but outbound scanning should also be scanned in case the company's email servers become SPAM relays and get blacklisted on sites such as Lashback or get blocked to external sites by force.
5. **Establish WPA2 encryption for Wi-Fi traffic access—**WPA2 for now is the best encryption available compared to WEP encryption, which is dated and not recommended.
6. **Establish logging metrics and granular controls—**Keeping regular tabs on information asset access by users and configuring alerting on unusual activity (such as large-scale access or exceeded failed-logon thresholds) is a good way to prevent data leakage.

Mobile devices accessing enterprise intranets using VPNs are subject to the same factors as any other device remotely accessing VPNs, namely (see Figure 13.3):

1. Protection of data while in transmission
2. Protection of data while at rest
3. Protection of the mobile device itself (in case it fell into the wrong hands)
4. App security

At a minimum, the following standards are recommended for managing tablets and smartphones with Mobile Device Management (MDM) appliances:

1. **Protection of data while in transmission:** Transmission security for mobile devices is concerned primarily with VPN security as well as Wi-Fi security. With regard to VPNs, the primary preference for most mobile devices should be for Web-based or SSL VPNs. The reason is that IPsec and L2TP VPN implementations are still buggy as of this writing on all but iOS devices (iPhones and iPads). SSL VPNs can also be implemented as clientless. Regarding Wi-F,i the choice is to simply configure WPA2 Enterprise using 128-bit AES encryption for mobile devices connecting via Wi-Fi. Again, MDM appliances can be used to push out these policies to the mobile devices.
2. **Protection of data while at rest:** The basis of protecting stored data on a mobile device is the password. The stronger the password, the harder to break the encryption. Some devices (including the iPad) support 256-bit AES encryption. Most recent mobile devices also support remote wipe and progressive wipe. The latter feature will progressively increase the time of the lockout duration until finally initiating an automatic remote wipe of all data on the device. These wipe features are designed to protect company data from falling into the wrong hands. All these features can be queried and are configurable for mobile devices via either Exchange ActiveSync policies or configuration policies from MDM appliances.
3. **Protection of the mobile device:** Passwords for mobile devices have to conform to the same corporate "strong password" policy as for other wired network devices. This means the password length, content (minimum of eight characters, alphanumeric, special characters etc.), password rotation and expiry (remember: last three and every two to three months), and

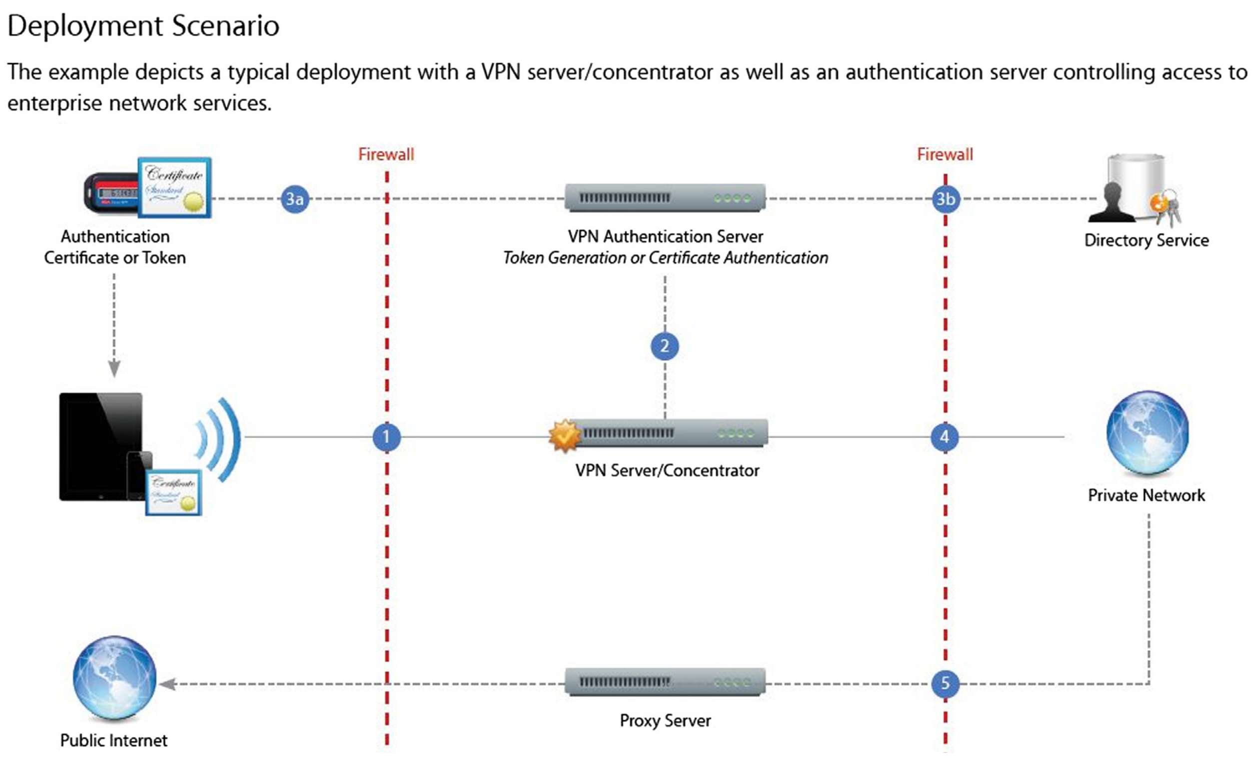

FIGURE 13.3 Mobile device VPN access to company network using token authentication *Courtesy: Apple Inc.*

password lockout (three to five attempts) have to be enforced. Complete sets of configuration profiles can be pushed to tablets, smartphones, and iPads using MDM appliances specifying app installation privileges, YouTube, and iTunes content ratings permissions, among many others.

4. **App security:** In recent versions of both Android and iOS, significant changes have been made so that app security has become more bolstered. For example, in both OSs, apps run in their own silos and can't access other app or system data. While iPhone apps are theoretically capable of accessing the users' contact information and also their locations in some cases, Apple's signing process for every app that appears in the iTunes app store takes care of this. It is possible on the iOS devices to encrypt data using either software methods such as AES, RC4, 3DES, or hardware accelerated encryption activated when a lockout occurs. In iOS, designating an app as managed can prevent its content from being uploaded to iCloud or iTunes. In this manner, MDM appliances or Exchange ActiveSync can prevent leakage of sensitive company data.

While there are quite a few risks in deploying mobile devices within the Intranet, with careful configuration these risks can be minimized to the point where the myriad benefits outweigh the risks. One thing is certain: These mobile devices and the efficiency they promise are for real, and they are not going away.

Empowering employees is the primary idea in the popularity of these devices. And corporate IT will only serve its own interest by designing enabling security around these devices and letting employees be more productive.

3. PLUGGING THE GAPS: NAC AND ACCESS CONTROL

The first priority of an information security officer in most organizations is to ensure that there is a relevant corporate policy on access controls. Simple on the surface, the subject of access control is often complicated by the variety of ways the intranet is connected to the external world.

Remote users coming in through traditional or SSL (browser-based) virtual private networks (VPNs), control over use of USB keys, printouts, and CD-ROMs all require that a comprehensive endpoint security solution be implemented.

The past couple of years have seen large-scale adoption of network access control (NAC) products in the midlevel and larger IT shops to manage endpoint security. Endpoint security ensures that whoever is plugging into or accessing any hardware anywhere within the intranet

has to comply with the minimum baseline corporate security policy standards. This can include add-on access credentials but goes far beyond access. Often these solutions ensure that traveling corporate laptops are compliant with a minimum patching level, scans, and antivirus definition levels before being allowed to connect to the intranet.

The NAC appliances that enforce these policies often require that a NAC fat client is installed on every PC and laptop. This rule can be enforced during logon using a logon script. The client can also be part of the standard OS image for deploying new PCs and laptops.

Microsoft has built an NAC-type framework into some versions of its client OSs (Vista and XP SP3) to ease compliance with its NAC server product called MS Network Policy Server, which closely works with its Windows 2008 Server product (see sidebar: The Cost of a Data Breach). The company has been able to convince quite a few industry networking heavyweights (notably Cisco and Juniper) to adopt its NAP standard.[22]

The Cost of a Data Breach

As of July 2007, the average breach cost per incident was $4.8 million.

- This works out to $182 per exposed record.
- It represents an increase of more than 30 percent from 2005.
- Thirty-five percent of these breaches involved the loss or theft of a laptop or other portable device.
- Seventy percent were due to a mistake or malicious intent by an organization's own staff.
- Since 2005, almost 150 million individuals' identifiable information has been compromised due to a data security breach.
- Nineteen percent of consumers notified of a data breach discontinued their relationship with the business, and a further 40 percent considered doing so.[23]

Essentially, the technology has three parts: a policy-enforceable client, a decision point, and an enforcement point. The client could be an XP SP3 or Vista client (either a roaming user or guest user) trying to connect to the company intranet. The decision point in this case would be the Network Policy Server product, checking to see whether the client requesting access meets the minimum baseline to allow it to connect. If it does not, the decision point product would pass this data on to the enforcement point, a network access product such as a router or switch, which would then be able to cut off access.

The scenario would repeat itself at every connection attempt, allowing the network's health to be maintained on an ongoing basis. Microsoft's NAP page has more details and animation to explain this process.[24]

Access control in general terms is a relationship triad among internal users, intranet resources, and the actions internal users can take on those resources. The idea is to give users only the least amount of access they require to perform their job. The tools used to ensure this in Windows shops utilize Active Directory for Windows logon scripting and Windows user profiles. Granular classification is needed for users, actions, and resources to form a logical and comprehensive access control policy that addresses who gets to connect to what, yet keeping the intranet safe from unauthorized access or data-security breaches. Quite a few off-the-shelf solutions geared toward this market often combine inventory control and access control under a "desktop life-cycle" planning umbrella.

Typically, security administrators start with a "Deny-All" policy as a baseline before slowly building in the access permissions. As users migrate from one department to another, are promoted, or leave the company, in large organizations this job can involve one person by herself. This person often has a very close working relationship with Purchasing, Helpdesk, and HR, getting coordination and information from these departments on users who have separated from the organization and computers that have been surplused, deleting and modifying user accounts and assignments of PCs and laptops.

Helpdesk software usually has an inventory control component that is readily available to Helpdesk personnel to update and/or pull up to access details on computer assignments and user status. Optimal use of form automation can ensure that these details occur (such as deleting a user on the day of separation) to avoid any possibility of an unwelcome data breach.

4. MEASURING RISK: AUDITS

Audits are another cornerstone of a comprehensive intranet security policy. To start an audit, an administrator should know and list what he is protecting as well as know the relevant threats and vulnerabilities to those resources.

Assets that need protection can be classified as either tangible or intangible. *Tangible assets* are, of course, removable media (USB keys), PCs, laptops, PDAs, Web

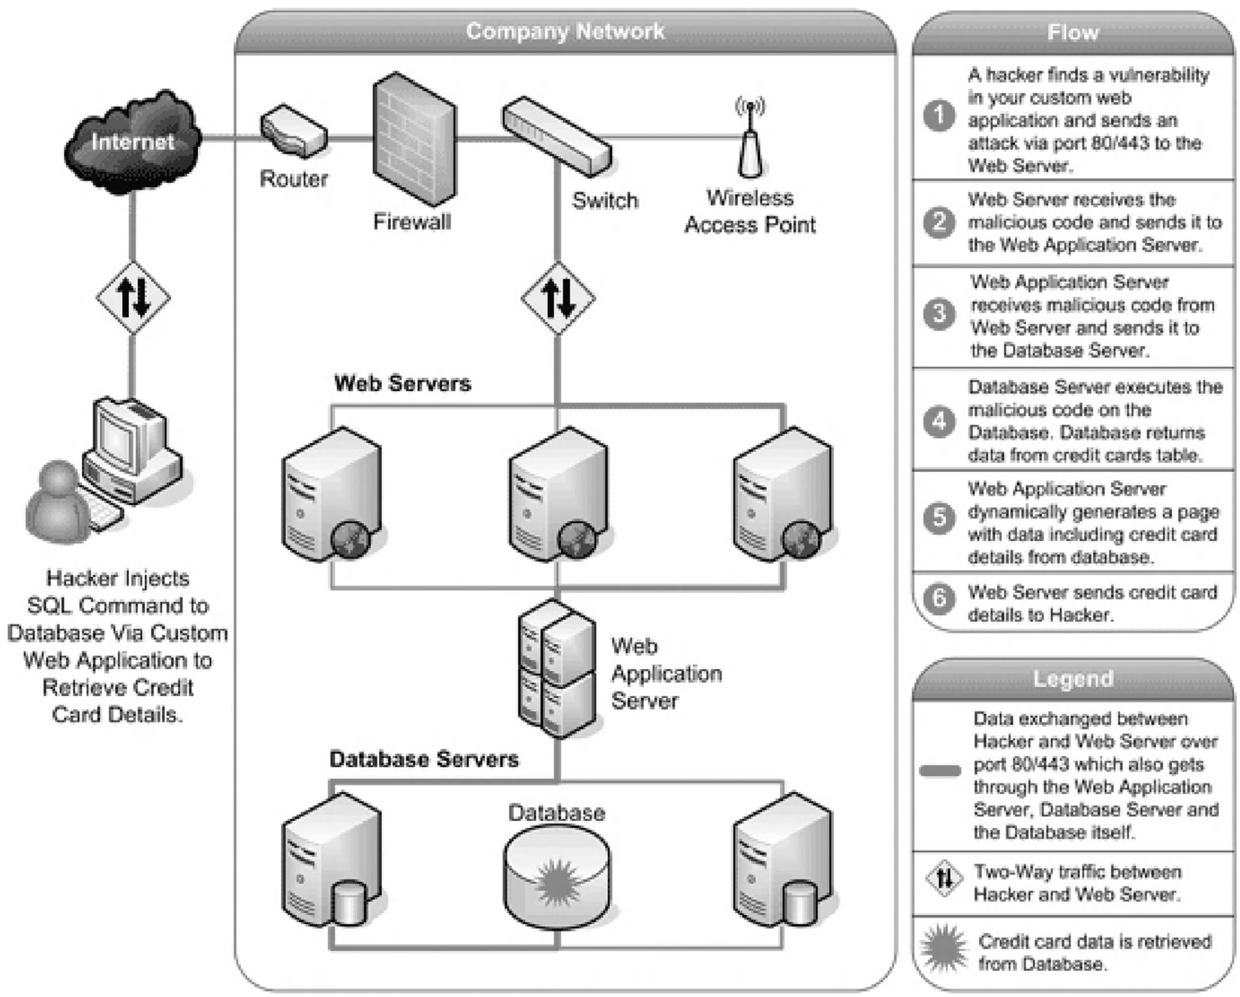

FIGURE 13.4 SQL injection attack. Source: © *acunetix.com*.

servers, networking equipment, DVR security cameras, and employees' physical access cards. *Intangible assets* can include company intellectual property such as corporate email and wikis, user passwords, and, especially for HIPAA and Sarbanes-Oxley mandates, personally identifiable health and financial information, which the company could be legally liable to protect.

Threats can include the theft of USB keys, laptops, PDAs, and PCs from company premises. This results in a data breach (for tangible assets), weak passwords, and unhardened operating systems in servers (for *intangible assets*).

Once a correlated listing of assets and associated threats and vulnerabilities has been made, we have to measure the impact of a breach, which is known as *risk*. The common rule of thumb to measure risk is:

$$\text{Risk} = \text{Value of asset} \times \text{Threat} \times \text{Vulnerability}$$

It is obvious that an Internet-facing Web server faces greater risk and requires priority patching and virus scanning because the vulnerability and threat components are high in that case (these servers routinely get sniffed and scanned over the Internet by hackers looking to find holes in their armor). However, this formula can standardize the priority list so that the actual audit procedure (typically carried out weekly or monthly by a vulnerability-scanning device) is standardized by risk level. Vulnerability-scanning appliances usually scan server farms and networking appliances only because these are high-value targets within the network for hackers who are looking for either unhardened server configurations or network switches with default factory passwords left on by mistake. To illustrate the situation, look at Figure 13.4, which illustrates an SQL injection attack on a corporate database.[25]

25. "Web Application Security—Check Your Site for Web Application Vulnerabilities," www.acunetix.com/websitesecurity/webapp-security.htm.

Questions for a Nontechnical Audit of Intranet Security

1. Is all access (especially to high-value assets) logged?
2. In case of laptop theft, is encryption enabled so that the records will be useless to the thief?
3. Are passwords verifiably strong enough to comply with the security policy? Are they changed frequently and held to strong encryption standards?
4. Are all tangible assets (PCs, laptops, PDAs, Web servers, networking equipment) tagged with asset tags?
5. Is the process for surplusing obsolete IT assets secure (that is, are disks wiped for personally identifiable data before surplusing happens)?
6. Are email and Web usage logged?
7. Are peer-to-peer (P2P) and instant messaging (IM) usage controlled?

Based on the answers you get (or don't get), you can start the security audit procedure by finding answers to these questions.

The value of an asset is subjective and can be assessed only by the IT personnel in that organization (see sidebar, Questions for a Nontechnical Audit of Intranet Security). If the IT staff has an ITIL (Information Technology Infrastructure Library) process under way, the value of an asset will often already have been classified and can be used. Otherwise, a small spreadsheet can be created with classes of various tangible and intangible assets (as part of a hardware/software cataloguing exercise) and values assigned that way.

5. GUARDIAN AT THE GATE: AUTHENTICATION AND ENCRYPTION

To most lay users, authentication in its most basic form is two-factor authentication—meaning a username and a password. Although adding further factors (such as additional autogenerated personal identification numbers [PINs] and/or biometrics) makes authentication stronger by magnitudes, one can do a lot with just the password within a two-factor situation. Password strength is determined by how hard the password is to crack using a password-cracker application that uses repetitive tries using common words (sometimes from a stored dictionary) to match the password. Some factors will prevent the password from being cracked easily and make it a stronger password:

- Password length (more than eight characters)
- Use of mixed case (both uppercase and lowercase)
- Use of alphanumeric characters (letters as well as numbers)
- Use of special characters (such as !, ?, %, and #)

The ACL in a Windows AD environment can be customized to demand up to all four factors in the setting or renewal of a password, which will render the password strong. Prior to a few years ago, the complexity of a password (the last three items in the preceding list) was favored as a measure of strength in passwords. However, the latest preference as of this writing is to use uncommon passwords—joined-together sentences to form passphrases that are quite long but don't have much in the way of complexity. Password authentication ("what you know") as two-factor authentication is not as secure as adding a third factor to the equation (a dynamic token password). Common types of third-factor authentication include biometrics (fingerprint scan, palm scan, or retina scan—in other words, "what you are") and token-type authentication (software or hardware PIN−generating tokens—that is, "what you have"). Proximity or magnetic swipe cards and tokens have seen common use for physical premises-access authentication in high-security buildings (such as financial and R & D companies), but not for network or hardware access within IT.

When remote or teleworker employees connect to the intranet via VPN tunnels or Web-based SSL VPNs (the outward extension of the intranet once called an *extranet*), the connection needs to be encrypted with strong 3DES or AES type encryption to comply with patient data and financial data privacy mandates. The standard authentication setup is usually a username and a password, with an additional hardware token-generated random PIN entered into a third box. Until lately, RSA as a company was one of the bigger players in the hardware-token field; incidentally, it also invented the RSA algorithm for public-key encryption.

As of this writing, hardware tokens cost under $30 per user in quantities of greater than a couple hundred pieces, compared to about a $100 only a decade ago. Most vendors offer free lifetime replacements for hardware tokens. Instead of a separate hardware token, some inexpensive software token generators can be installed within PC clients, smartphones, and BlackBerry devices. Tokens are probably the most cost-effective enhancement to security today.

6. WIRELESS NETWORK SECURITY

Employees using the convenience of wireless to log into the corporate network (usually via laptop) need to have their laptops configured with strong encryption to prevent data breaches. The first-generation encryption type known as Wireless Equivalent Privacy (WEP) was easily

deciphered (cracked) using common hacking tools and is no longer widely used. The latest standard in wireless authentication is WPA or WPA2 (802.11i), which offers stronger encryption compared to WEP. Although wireless cards in laptops can offer all the previously noted choices, they should be configured with WPA or WPA2 if possible.

There are quite a few hobbyists roaming corporate areas looking for open wireless access points (transmitters) equipped with powerful Wi-Fi antennas and wardriving software, a common package being Netstumbler. Wardriving was originally meant to log the presence of open Wi-Fi access points on Web sites (see sidebar: Basic Ways to Prevent Wi-Fi Intrusions in Corporate Intranets), but there is no guarantee that actual access and use (*piggybacking*, in hacker terms) won't occur, curiosity being human nature. If there is a profit motive, as in the TJX example, access to corporate networks will take place, although the risk of getting caught and the resulting risk of criminal prosecution will be high. Furthermore, installing a RADIUS server is a must to check access authentication for roaming laptops.

7. SHIELDING THE WIRE: NETWORK PROTECTION

Firewalls are, of course, the primary barrier to a network. Typically rule based, firewalls prevent unwarranted traffic from getting into the intranet from the Internet. These days firewalls also do some stateful inspections within packets to peer a little into the header contents of an incoming packet, to check validity—that is, to check whether a streaming video packet is really what it says it is, and not malware masquerading as streaming video.

Intrusion prevention systems (IPSs) are a newer type of inline network appliance that uses heuristic analysis (based on a weekly updated signature engine) to find patterns of malware identity and behavior and to block malware from entering the periphery of the intranet. The IPS and the intrusion detection system (IDS), however, operate differently.

IDSs are typically *not* sitting inline; they sniff traffic occurring anywhere in the network, cache extensively, and can correlate events to find malware. The downside

Basic Ways to Prevent Wi-Fi Intrusions in Corporate Intranets

1. Reset and customize the default Service Set Identifier (SSID) or Extended Service Set Identifier (ESSID) for the access point device before installation.
2. Change the default admin password.
3. Install a RADIUS server, which checks for laptop user credentials from an Active Directory database (ACL) from the same network before giving access to the wireless laptop. See Figures 13.5 and 13.6 for illustrated explanations of the process.
4. Enable WPA or WPA2 encryption, not WEP, which is easily cracked.
5. Periodically try to wardrive around your campus and try to sniff (and disable) nonsecured network-connected rogue access points set up by naïve users.
6. Document the wireless network by using one of the leading wireless network management software packages made for that purpose.

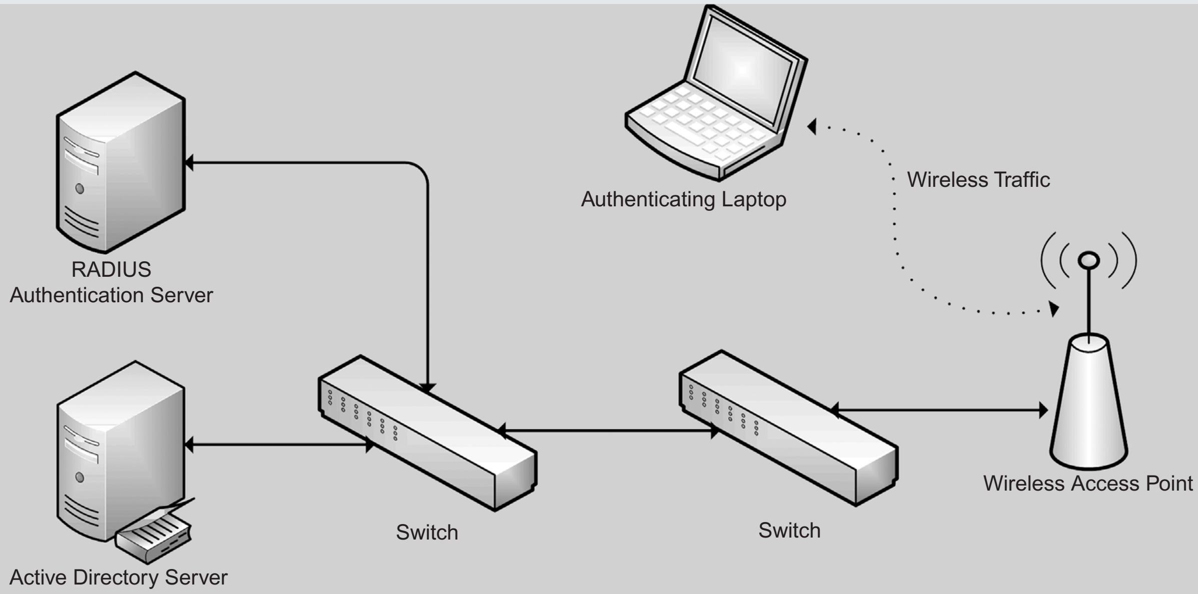

FIGURE 13.5 Wireless EAP authentication using Active Directory and authentication servers.

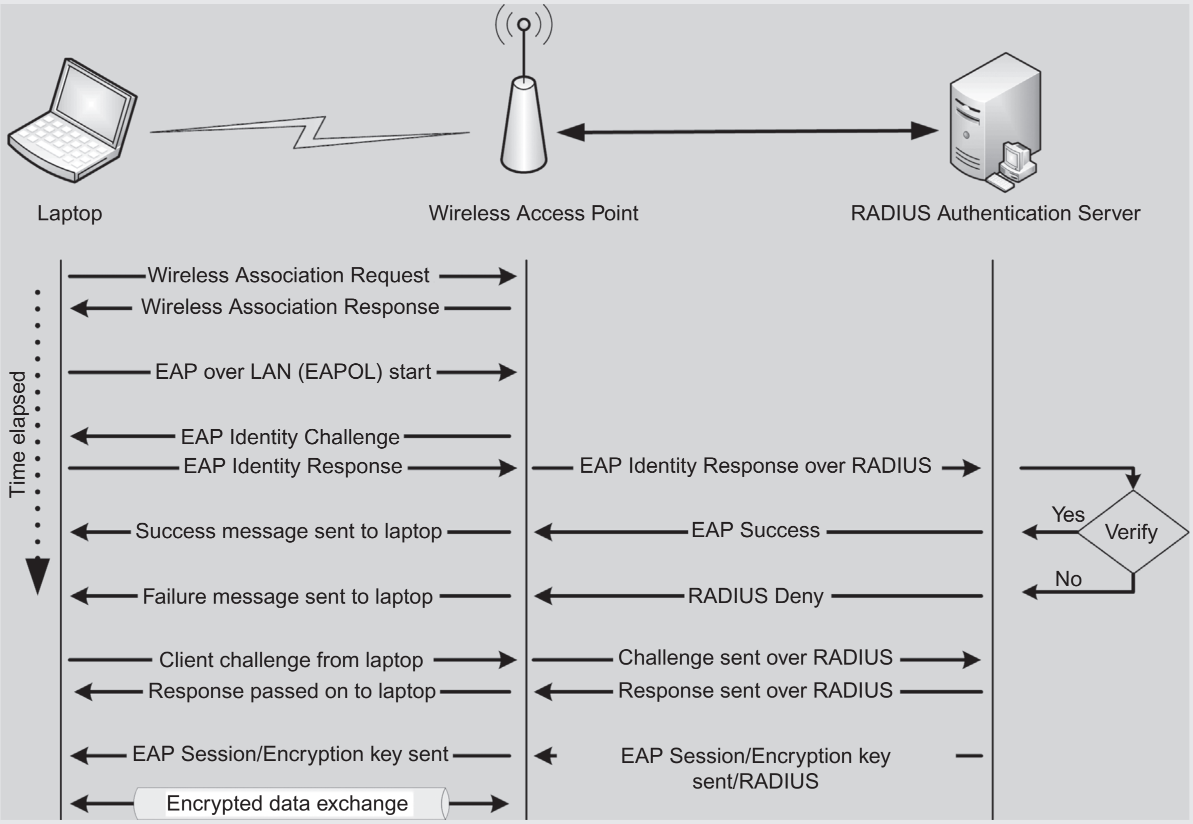

FIGURE 13.6 High-level wireless Extensible Authentication Protocol (EAP) workflow.

Note: Contrary to common belief, turning off the SSID broadcast won't help unless you're talking about a home access point situation. Hackers have an extensive suite of tools with which to sniff SSIDs for lucrative corporate targets, which will be broadcast anyway when connecting in clear text (unlike the real traffic, which will be encrypted).

of IDSs is that unless their filters are extensively modified, they generate copious amounts of false positives—so much so that "real" threats become impossible to sift out of all the noise.

IPSs, in contrast, work *inline* and inspect packets rapidly to match packet signatures. The packets pass through many hundreds of parallel filters, each containing matching rules for a different type of malware threat. Most vendors publish new sets of malware signatures for their appliances every week. However, signatures for common worms and injection exploits such as SQL-slammer, Code-red, and NIMDA are sometimes hardcoded into the application-specific integrated chip (ASIC) that controls the processing for the filters. Hardware-enhancing a filter helps avert massive-scale attacks more efficiently because it is performed in hardware, which is more rapid and efficient compared to software signature matching. Incredible numbers of malicious packets can be dropped from the wire using the former method.

The buffers in an enterprise-class IPS are smaller than those in IDSs and are quite fast—akin to a high-speed switch to preclude latency (often as low as 200 microseconds during the highest load). A top-of-the-line mid-size IPS box's total processing threshold for all input and output segments can exceed 5 gigabits per second using parallel processing.[26]

However, to avoid overtaxing CPUs and for efficiency's sake, IPSs usually block only a very limited number of important threats out of the thousands of malware signatures listed. Tuning IPSs can be tricky—just enough blocking to silence the false-positive noise but making sure all critical filters are activated to block important threats.

Types of Redundancy for Inline Security Appliances

1. Security appliances usually have dual power supplies (often hot-swappable) and are designed to be connected to two separate UPS devices, thereby minimizing the chances of a failure within the appliance itself. The hot-swap capability minimizes replacement time for power supplies.
2. We can configure most of these appliances to either shut down the connection or fall back to a level-two switch (in case of hardware failure). If reverting to a fallback state, most IPSs become basically a bump in the wire and, depending on the type of traffic, can be configured to fail open so that traffic remains uninterrupted. Also, inexpensive, small third-party switchboxes are available to enable this failsafe high-availability option for a single IPS box. The idea is to keep traffic flow active regardless of attacks.
3. IPS or firewall devices can be placed in dual-redundant fail-over mode, either in active-active (load-sharing) or active-passive (primary-secondary) mode. The devices commonly use a protocol called Virtual Router Redundancy Protocol (VRRP) where the secondary pings the primary every second to check live status and assumes leadership to start processing traffic in case pings are not returned from the primary. The switchover is instantaneous and transparent to most network users. Prior to the switchover, all data and connection settings are fully synchronized at identical states between both boxes to ensure failsafe switchover.
4. Inline IPS appliances are relatively immune to attacks because they have highly hardened Linus/Unix operating systems and are designed from the ground up to be robust and low-maintenance appliances (logs usually clear themselves by default).

The most important factors in designing a critical data infrastructure are resiliency, robustness, and redundancy regarding the operation of inline appliances. Whether one is talking about firewalls or inline IPSs, redundancy is paramount (see sidebar: Types of Redundancy for Inline Security Appliances). Intranet robustness is a primary concern where data has to available on a 24/7 basis.

Most security appliances come with syslog reporting (event and alert logs sent usually via port 514 UDP) and email notification (set to alert beyond a customizable threshold) as standard. The syslog reporting can be forwarded to a security event management (SEM) appliance, which consolidates syslogs into a central threat console for benefit of event correlation and forwards warning emails to administrators based on preset threshold criteria. Moreover, most firewalls and IPSs can be configured to forward their own notification email to administrators in case of an impending threat scenario.

For those special circumstances where a wireless-type LAN connection is the primary one (whether microwave beam, laser beam, or satellite-type connection), redundancy can be ensured by a secondary connection of equal or smaller capacity. For example, in certain northern Alaska towns where digging trenches into the hardened icy permafrost is expensive and rigging wire across the tundra is impractical due to the extreme cold, the primary network connections between towns are always via microwave link, often operating in dual redundant mode.

8. WEAKEST LINK IN SECURITY: USER TRAINING

Intranet security awareness is best communicated to users in two primary ways—during new employee orientation and by ongoing targeted training for users in various departments with specific user audiences in mind. A formal security training policy should be drafted and signed off by management, with well-defined scopes, roles, and responsibilities of various individuals, such as the CIO and the information security officer, and posted on the intranet. New recruits should be given a copy of all security policies to sign off on before they are granted user access. The training policy should also spell out the roles of the HR, Compliance, and PR departments in the training program.

Training can be given using the PowerPoint Seminar method in large gatherings before monthly “all-hands” departmental meetings and also via an emailed Web link to a Flash video format presentation. The latter can also be configured to have an interactive quiz at the end, which should pique audience interest in the subject and help them remember relevant issues.

With regard to topics to be included in the training, any applicable federal or industry mandate such as HIPAA, SOX, PCI-DSS, or ISO 27002 should be discussed extensively first, followed by discussions on tackling social engineering, spyware, viruses, and so on.

The topics of data theft and corporate data breaches are frequently in the news. These topics can be extensively discussed, with emphasis on how to protect personally identifiable information in a corporate setting. Password policy and access control topics are always good things to discuss; users at a minimum need to be reminded to sign off their workstations before going on break.

9. DOCUMENTING THE NETWORK: CHANGE MANAGEMENT

Controlling the IT infrastructure configuration of a large organization is more about change control than other

Change Management Spreadsheet Details to Submit to a CM Meeting

- Name and organizational details of the change-requestor
- Actual change details, such as the time and duration of the change
- Any possible impacts (high, low, medium) to significant user groups or critical functions
- The amount of advance notice needed for impacted users via email (typically two working days)
- Evidence that the change has been tested in advance
- Signature and approval of the supervisor and her supervisor (manager)
- Whether and how rollback is possible
- Post-change, a "postmortem tab" has to confirm whether the change process was successful and any revealing comments or notes for the conclusion.
- One of the tabs can be an "attachment tab" containing embedded Visio diagrams or word documentation embedded within the Excel sheet to aid discussion.

things. Often the change control guidance comes from documents such as the ITIL series of guidebooks.

After a baseline configuration is documented, change control—a deliberate and methodical process that ensures that any changes are made to the baseline IT configuration of the organization (such as changes to network design, AD design, and so on)—is extensively documented and authorized only after prior approval. This is done to ensure that unannounced or unplanned changes are not allowed to hamper the day-to-day efficiency and business functions of the overall intranet infrastructure.

In most government entities, even very small changes are made to go through change management (CM); however, management can give managers leeway to approve a certain minimal level of ad hoc change that has no potential to disrupt operations. In most organizations where mandates are a day-to-day affair, no ad hoc change is allowed unless it goes through supervisory-level change management meetings.

The goal of change management is largely to comply with mandates—but for some organizations, waiting for a weekly meeting can slow things significantly. If justified, an emergency CM meeting can be called to approve a time-sensitive change.

Practically speaking, the change management process works as follows: A formal change management document is filled out (usually a multitab online Excel spreadsheet) and forwarded to the change management ombudsman (maybe a project management person). For some CM form details, see the sidebar: Change Management Spreadsheet Details to Submit to a CM Meeting.

The document must have supervisory approval from the requestor's supervisor before proceeding to the ombudsman. The ombudsman posts this change document on a section of the intranet for all other supervisors and managers within the CM committee to review in advance. Done this way, the change management committee, meeting in its weekly or biweekly change approval meetings, can voice reservations or ask clarification questions of the change-initiating person, who is usually present to explain the change. At the end of the deliberations the decision is then voted on to either approve, deny, modify, or delay the change (sometimes with preconditions).

If approved, the configuration change is then made (usually within the following week). The postmortem section of the change can then be updated to note any issues that occurred during the change (such as a rollback after change reversal and the causes).

In recent years, some organizations have started to operate the change management collaborative process using social networking tools at work. This allows disparate flows of information, such as emails, departmental wikis, and file-share documents, to belong to a unified thread for future reference.

10. REHEARSE THE INEVITABLE: DISASTER RECOVERY

Possible disaster scenarios can range from the mundane to the biblical in proportion. In intranet or general IT terms, successfully recovering from a disaster can mean resuming critical IT support functions for mission-critical business functions. Whether such recovery is smooth and hassle-free depends on how prior disaster-recovery planning occurs and how this plan is tested to address all relevant shortcomings adequately.

The first task when planning for disaster recovery (DR) is to assess the business impact of a certain type of disaster on the functioning of an intranet using business impact analysis (BIA). BIA involves certain metrics; again, off-the shelf software tools are available to assist with this effort. The scenario could be a natural hurricane-induced power outage or a human-induced critical application crash. In any one of these scenarios, one needs to assess the type of impact in time, productivity, and financial terms.

BIAs can take into consideration the breadth of impact. For example, if the power outage is caused by a hurricane or an earthquake, support from generator vendors or the electricity utility could be hard to get, because

of the large demands for their services. BIAs also need to take into account historical and local weather priorities. Though there could be possibilities of hurricanes occurring in California or earthquakes occurring along the Gulf Coast of Florida, for most practical purposes the chances of those disasters taking place in those locales are pretty remote. Historical data can be helpful for prioritizing contingencies.

Once the business impacts are assessed to categorize critical systems, a disaster recovery (DR) plan can be organized and tested. The criteria for recovery have two types of metrics: a recovery point objective (RPO) and a recovery time objective (RTO).

In the DR plan, the RPO refers to how far back or "back to what point in time" that backup data has to be recovered. This timeframe generally dictates how often tape backups are taken, which can again depend on the criticality of the data. The most common scenario for medium-sized IT shops is daily incremental backups and a weekly full backup on tape. Tapes are sometimes changed automatically by the tape backup appliances.

One important thing to remember is to rotate tapes (that is, put them on a life-cycle plan by marking them for expiry) to make sure that tapes have complete data integrity during a restore. Most tape manufacturers have marking schemes for this task. Although tapes are still relatively expensive, the extra amount spent on always having fresh tapes ensures that there are no nasty surprises at the time of a crucial data recovery.

RTO refers to how long it takes to restore backed up or recovered data to its original state for resuming normal business processes. The critical factor here is cost. It will cost much more to restore data within an hour using an online backup process or to resume operations using a hotsite rather than a five-hour restore using stored tape backups. If business process resumption is critical, cost becomes a less important factor.

DR also has to take into account resumption of communication channels. If network and telephone links aren't up, having a timely tape restore does little good to resume business functions. Extended campus network links are often dependent on leased lines from major vendors such as Verizon and AT & T, so having a trusted vendor relationship with agreed-on SLA standards is a requirement.

Depending on budgets, one can configure DR to happen almost instantly, if so desired, but that is a far more costly option. Most shops with "normal" data flows are okay with business being resumed within the span of about three to fours hours or even a full working day after a major disaster. Balancing costs with business expectations is the primary factor in the DR game. Spending inordinately for a rare disaster that might never happen is a waste of resources. It is fiscally imprudent (not to mention futile) to try to prepare for every contingency possible.

Once the DR plan is more or less finalized, a DR committee can be set up under an experienced DR professional to orchestrate the routine training of users and managers to simulate disasters on a frequent basis. In most shops this means management meeting every two months to simulate a DR "war room" (command center) situation and employees going through a mandatory interactive six-month disaster recovery training, listing the DR personnel to contact.

Within the command center, roles are preassigned, and each member of the team carries out his or her role as though it were a real emergency or disaster. DR coordination is frequently modeled after the U.S. Federal Emergency Management Agency (FEMA) guidelines, an active entity that has training and certification tracks for DR management professionals.

Simulated "generator shutdowns" in most shops are scheduled on a biweekly or monthly basis to see how the systems actually function. The systems can include uninterrupible power supplies (UPSs), emergency lighting, email and cell phone notification methods, and alarm enunciators and sirens. Since electronics items in a server room are sensitive to moisture damage, gas-based Halon fire-extinguishing systems are used. These Halon systems also have a provision to test them (often twice a year) to determine their readiness. The vendor will be happy to be on retainer for these tests, which can be made part of the purchasing agreement as a service level agreement (SLA). If equipment is tested on a regular basis, shortcomings and major hardware maintenance issues with major DR systems can be easily identified, documented, and redressed.

In a severe disaster situation, priorities need to be exercised on what to salvage first. Clearly, trying to recover employee records, payroll records, and critical business mission data such as customer databases will take precedence. Anything irreplaceable or not easily replaceable needs priority attention.

We can divide the levels of redundancies and backups to a few progressive segments. The level of backup sophistication would of course be dependent on (1) criticality and (2) time-to-recovery criteria of the data involved.

At the very basic level, we can opt not to back up any data or not even have procedures to recover data, which means that data recovery would be a failure. Understandably, this is not a common scenario.

More typical is contracting with an archival company of a local warehouse within a 20-mile periphery. Tapes are backed up onsite and stored offsite, with the archival company picking up the tapes from your facility on a daily basis. The time to recover is dependent on retrieving the tapes from archival storage, getting them onsite, and starting a restore. The advantages here are lower cost.

However, the time needed to transport tapes and recover them might not be acceptable, depending on the type of data and the recovery scenario.

Often a “coldsite” or “hotsite” is added to the intranet backup scenario. A coldsite is a smaller and scaled-down copy of the existing intranet data center that has only the most essential pared-down equipment supplied and tested for recovery but not in a perpetually ready state (powered down as in “cold,” with no live connection). These coldsites can house the basics, such as a Web server, domain name servers, and SQL databases, to get an informational site started up in very short order.

A hotsite is the same thing as a coldsite except that in this case the servers are always running and the Internet and intranet connections are “live” and ready to be switched over much more quickly than on a coldsite. These are just two examples of how the business resumption and recovery times can be shortened.

Recovery can be made very rapidly if the hotsite is linked to the regular data center using fast leased-line links (such as a DS3 connection). Backups synched in real time with identical RAID disks at the hotsite over redundant high-speed data links afford the shortest recovery time.

In larger intranet shops based in defense-contractor companies, there are sometimes requirements for even faster data recovery with far more rigid standards for data integrity. To-the-second real-time data synchronization in addition to hardware synchronization ensures that duplicate sites thousands of miles away can be up and running within a matter of seconds—even faster than a hotsite. Such extreme redundancy is typically needed for critical national databases (that is, air traffic control or customs databases that are accessed 24/7, for example).

At the highest level of recovery performance, most large database vendors offer “zero data loss” solutions, with a variety of cloned databases synchronized across the country that automatically failover and recover in an instantaneous fashion to preserve a consistent status—often free from human intervention. Oracle’s version is called Data Guard; most mainframe vendors offer a similar product, varying in their offerings of tiers and features.

The philosophy here is simple: The more dollars you spend, the more readiness you can buy. However, the expense has to be justified by the level of criticality for the availability of the data.

11. CONTROLLING HAZARDS: PHYSICAL AND ENVIRONMENTAL PROTECTION

Physical access and environmental hazards are very relevant to security within the intranet. People are the primary weak link in security (as previously discussed), and controlling the activity and movement of authorized personnel and preventing access to unauthorized personnel fall within the purview of these security controls. This important area of intranet security must first be formalized within a management-sanctioned and published P&P.

Physical access to data center facilities (as well as IT working facilities) is typically controlled using card readers. These were scanning types in the last two decades but are increasingly being converted to near-field or proximity-type access card systems. Some high-security facilities (such as bank data centers) use smartcards, which use encryption keys stored within the cards for matching keys.

Some important and common-sense topics should be discussed within the subject of physical access. First, disbursal of cards needs to be a deliberate and high-security affair requiring the signatures of at least two supervisory-level people who can be responsible for the authenticity and actual need for access credentials for a person to specific areas.

Access-card permissions need to be highly granular. An administrative person will probably never need to be in the server room, so that person’s access to the server room should be blocked. Areas should be categorized and catalogued by sensitivity and access permissions granted accordingly.

Physical data transmission access points to the intranet have to be monitored via digital video recording (DVR) and closed-circuit cameras if possible. Physical electronic eavesdropping can occur to unmonitored network access points in both wireline and wireless ways. There have been known instances of thieves intercepting LAN communication from unshielded Ethernet cable (usually hidden above the plenum or false ceiling for longer runs). All a data thief needs is to place a TAP box and a miniature (Wi-Fi) wireless transmitter at entry or exit points to the intranet to copy and transmit all communications. At the time of this writing, these transmitters are the size of a USB key. The miniaturization of electronics has made data theft possible for part-time thieves. Spy-store sites give determined data thieves plenty of workable options at relatively little cost.

Using a DVR solution to monitor and store access logs to sensitive areas and correlating them to the timestamps on the physical access logs can help forensic investigations in case of a physical data breach, malfeasance, or theft. It is important to remember that DVR records typically rotate and are erased every week. One person has to be in charge of the DVR so records are saved to optical disks weekly before they are erased. DVR tools need some tending to because their sophistication level often does not come up to par with other network tools.

Written or PC-based sign-in logs must be kept at the front reception desk, with timestamps. Visitor cards should have limited access to private and/or secured areas. Visitors must provide official identification, log times coming in and going out, and names of persons to be visited and the reason for their visit. If possible, visitors should be escorted to and from the specific person to be visited, to minimize the chances of subversion or sabotage.

Entries to courthouses and other special facilities have metal detectors, but these may not be needed for every facility. The same goes for bollards and concrete entry barriers to prevent car bombings. In most government facilities where security is paramount, even physical entry points to parking garages have special personnel (usually deputed from the local sheriff's department) to check under cars for hidden explosive devices.

Contractor laptops must be registered and physically checked in by field support personnel. And if these laptops are going to be plugged into the local network, the laptops need to be virus-scanned by data-security personnel and checked for unauthorized utilities or suspicious software (such as hacking utilities, Napster, or other P2P threats).

Supply of emergency power to the data center and the servers has to be robust to protect the intranet from corruption due to power failures. Redundancy has to be exercised all the way from the utility connection to the servers themselves. This means there has to be more than one power connection to the data center (from more than one substation/transformer, if it is a larger data center). There has to be provision of alternate power supply (a ready generator to supply some, if not all, power requirements) in case of power failure.

Power supplied to the servers has to come from more than one single UPS because most servers have two removable power inputs. Data center racks typically have two UPSs on the bottom supplying power to two separate power strips on both sides of the rack for this redundancy purpose (for seamless switchover). In case of a power failure, the UPSs instantly take over the supply of power and start beeping, alerting personnel to gracefully shut down servers. UPSs usually have reserve power for brief periods (less than 10 minutes) until the generator kicks in, relieving the UPS of the large burden of the server power loads. Generators come on trailers or are skid-mounted and are designed to run as long as fuel is available in the tank, which can be about three to five days, depending on the model and capacity to generate (in thousands of kilowatts).

Increasingly, expensive polluting batteries have made UPSs in larger data centers fall out of favor compared to flywheel power supplies, which are a cleaner, battery-less technology to supply interim power. Maintenance of this technology is half as costly as UPS, and it offers the same functionality. Provision has to be made for rechargeable emergency luminaires within the server room, as well as all areas occupied by administrators, so entry and exit are not hampered during a power failure.

Provision for fire detection and firefighting must also be made. As mentioned previously, Halon gas fire-suppression systems are appropriate for server rooms because sprinklers will inevitably damage expensive servers if the servers are still turned on during sprinkler activation.

Sensors have to be placed close to the ground to detect moisture from plumbing disasters and resultant flooding. Master shutoff valve locations for water have to be marked and identified and personnel trained on performing shutoffs periodically. Complete environmental control packages with cameras geared toward detecting any type of temperature, moisture, and sound abnormality are offered by many vendors. These sensors are connected to monitoring workstations using Ethernet LAN cabling. Reporting can occur through emails if customizable thresholds are met or exceeded.

12. KNOW YOUR USERS: PERSONNEL SECURITY

Users working within intranet-related infrastructures have to be known and trusted. Often data contained within the intranet is highly sensitive, such as new product designs and financial or market-intelligence data gathered after much research and at great expense.

Assigning personnel to sensitive areas in IT entails attaching security categories and parameters to the positions, especially within IT. Attaching security parameters to a position is akin to attaching tags to a photograph or blog. Some parameters will be more important than others, but all describe the item to some extent. The categories and parameters listed on the personnel access form should correlate to access permissions to sensitive installations such as server rooms. Access permissions should be compliant to the organizational security policy in force at the time. Personnel, especially those who will be handling sensitive customer data or individually identifiable health records, should be screened before hiring to ensure that they do not have felonies or misdemeanors on their records.

During transfers and terminations, all sensitive access tools should be reassessed and reassigned (or de-assigned, in case termination happens) for logical and physical access. Access tools can include such items as encryption tokens, company cell phones, laptops or PDAs, card keys, metal keys, entry passes, and any other company identification provided for employment. For people who are leaving the organization, an exit interview should be taken. System access should be terminated on the hour after former personnel have ceased to be employees of the company.

13. PROTECTING DATA FLOW: INFORMATION AND SYSTEM INTEGRITY

Information integrity protects information and data flows while they are in movement to and from the users' desktops to the intranet. System integrity measures protect the systems that process the information (usually servers such as email or file servers). The processes to protect information can include antivirus tools, IPS and IDS tools, Web-filtering tools, and email encryption tools.

Antivirus tools are the most common security tools available to protect servers and users' desktops. Typically, enterprise-level antivirus software from larger vendors such as Symantec or McAfee will contain a console listing all machines on the network and will enable the administrators to see graphically (color or icon differentiation) which machines need virus remediation or updates. All machines will have a software client installed that does some scanning and reporting of the individual machines to the console. To save bandwidth, the management server that contains the console will be updated with the latest virus (and spyware) definition from the vendor. Then it is the management console's job to slowly update the software client in each computer with the latest definitions. Sometimes the client itself will need an update, and the console allows this to be done remotely.

IDS detects malware within the network from the traffic and communication malware used. There are certain patterns of behavior attached to each type of malware, and those signatures are what IDSs are used to match. IDSs are mostly defunct nowadays. The major problems with IDSs were that (1) IDSs used to produce too many false positives, which made sifting out actual threats a huge, frustrating exercise, and (2) IDSs had no teeth; that is, their functionality was limited to reporting and raising alarms. IDS devices could not stop malware from spreading because they could not block it.

Compared to IDSs, IPSs have seen much wider adoption across corporate intranets because IPS devices sit inline processing traffic at the periphery and they can block traffic or malware, depending on a much more sophisticated heuristic algorithm than IDS devices. Although IPSs are all mostly signature based, there are already experimental IPS devices that can stop threats, not on signature, but based only on suspicious or anomalous behavior. This is good news because the numbers of "zero-day" threats are on the increase, and their signatures are mostly unknown to the security vendors at the time of infection.

Web-filtering tools have gotten more sophisticated as well. Ten years ago Web filters could only block traffic to specific sites if the URL matched. Today most Web filter vendors have large research arms that try to categorize specific Web sites under certain categories. Some vendors have realized the enormity of this task and have allowed the general public to contribute to this effort. The Web site www.trustedsource.org is an example; a person can go in and submit a single or multiple URLs for categorization. If they're examined and approved, the site category will then be added to the vendor's next signature update for their Web filter solution.

Web filters not only match URLs, but they also do a fair bit of packet-examining these days—just to make sure that a JPEG frame is indeed a JPEG frame and not a worm in disguise. The categories of Web sites blocked by a typical midsized intranet vary, but some surefire blocked categories would be pornography, erotic sites, discrimination/hate, weapons/illegal activities, and dating/relationships.

Web filters are not just there to enforce the moral values of management. These categories—if not blocked at work—openly enable an employee to offend another employee (especially pornography or discriminatory sites) and are fertile grounds for a liability lawsuit against the employer.

Finally, email encryption has been in the news because of the various mandates such as Sarbanes-Oxley and HIPAA. Both mandates specifically mention email or communication encryption to encrypt personally identifiable financial or patient medical data while in transit. Lately, the state of California (among other states) has adopted a resolution to discontinue fund disbursements to any California health organization that does not use email encryption as a matter of practice. This has caught quite a few California companies and local government entities unaware because email encryption software is relatively hard to implement. The toughest challenge yet is to train users to get used to the tool. Email encryption works by entering a set of credentials to access the email rather than just getting email pushed to the user, as within the email client Outlook.

14. SECURITY ASSESSMENTS

A security assessment (usually done on a yearly basis for most midsized shops) not only uncovers various misconfigured items on the network and server-side sections of IT operations; it also serves as a convenient blueprint for IT to activate necessary changes and get credibility for budgetary assistance from the accounting folks.

Typically, most consultants take two to four weeks to conduct a security assessment (depending on the size of the intranet), and they primarily use open-source vulnerability scanners such as Nessus. GFI LANguard, Retina, and Core Impact are other examples of commercial vulnerability-testing tools. Sometimes testers also use other proprietary suites of tools (special open-source tools

Types of Scans Conducted on Servers and Network Appliances during a Security Assessment

- Firewalls and IPS devices configuration
- Regular and SSL VPN configuration
- Web server hardening (most critical; available as guides from vendors such as Microsoft)
- DMZ configuration
- Email vulnerabilities
- DNS server anomalies
- Database servers (hardening levels)
- Network design and access control vulnerabilities
- Internal PC health such as patching levels and incidence of spyware, malware, and so on

like the Metasploit Framework or Fragrouter) to conduct "payload-bearing attack exploits," thereby evading the firewall and the IPS to gain entry. In the case of intranet Web servers, cross-site scripting attacks can occur (see sidebar: Types of Scans Conducted on Servers and Network Appliances during a Security Assessment).

The results of these penetration tests are usually compiled as two separate items: (1) as a full-fledged technical report for IT and (2) as a high-level executive summary meant for and delivered to top management to discuss strategy with IT after the engagement.

15. RISK ASSESSMENTS

Risk is defined as the probability of loss. In IT terms we're talking about compromising data CIA (confidentiality, integrity, or availability). Risk management is a way to manage the probability of threats causing an impact. Measuring risks using a risk assessment exercise is the first step toward managing or mitigating a risk. Risk assessments can identify network threats, their probabilities, and their impacts. The reduction of risk can be achieved by reducing any of these three factors.

Regarding intranet risks and threats, we're talking about anything from threats such as unpatched PCs getting viruses and spyware (with hidden keylogging software) to network-borne denial-of-service attacks and even large, publicly embarrassing Web vandalism threats, such as someone being able to deface the main page of the company Web site. The last is a very high-impact threat but mostly perceived to be a remote probability—unless, of course, the company has experienced this before. The awareness among vendors as well as users regarding security is at an all-time high due to security being a high-profile news item.

Any security threat assessment needs to explore and list exploitable vulnerabilities and gaps. Many midsized IT shops run specific vulnerability assessment (VA) tools in-house on a monthly basis. eEye's Retina Network Security Scanner and Foundstone's scanning tools appliance are two examples of VA tools that can be found in use at larger IT shops. These tools are consolidated on ready-to-run appliances that are usually managed through remote browser-based consoles. Once the gaps are identified and quantified, steps can be taken to gradually mitigate these vulnerabilities, minimizing the impact of threats.

In intranet risk assessments, we identify primarily Web server and database threats residing within the intranet, but we should also be mindful about the periphery to guard against breaches through the firewall or IPS.

Finally, making intranet infrastructure and applications can be a complex task. This gets even more complex and even confusing when information is obtained

An Agenda for Action for Intranet Security Implementation Process Activities

The following high-level checklist should be addressed in order to find the following intranet security implemnetation process questions helpful (check all tasks completed):

_____**1.** How to validate the intranet?
_____**2.** How to validate web applications?
_____**3.** How to ensure and verify accuracy of file transfer through the e-mails?
_____**4.** Does one need third-party certificates for digital signatures?
_____**5.** How to ensure limited and authorized access to closed and open systems?
_____**6.** How can one safely access the company intranet while traveling?
_____**7.** How to best protect the intranet from Internet attacks?
_____**8.** How to handle security patches?
_____**9.** Does the stakeholder expect to be able to find a procedure using a simple search interface?
_____**10.** How many documents will be hosted?
_____**11.** What design will be used (centralized, hub and spoke, etc.)?
_____**12.** Who will be involved in evaluating projects?
_____**13.** What is the budget?
_____**14.** Who will be responsible for maintaining the site after it goes "live"?

from the different sources that are normally found at security conferences around the world. Frequently, these conference sources give a high-level overview, talking about generic compliance; but none gives a full picture and details that are required for quick implementation. So, with the preceding in mind, and because of the frequency of poor security practices or far-too-common security failures on the intranet, let's briefly look at an intranet security implementation process checklist.

16. INTRANET SECURITY IMPLEMENTATION PROCESS CHECKLIST

With this checklist, you get all of your questions in one place. This not only saves time, it's also cost effective. The following high-level checklist lists all of the questions that are typically raised during the implementation process (see checklist: An Agenda for Action for Intranet Security Implementation Process Activities).

17. SUMMARY

It is true that the level of Internet hyperconnectivity among generation X and Y users has mushroomed lately, and the network periphery that we used to take for granted as a security shield has been diminished largely because of the explosive growth of social networking and the resulting connectivity boom. However, with the various new types of incoming application traffic (VoIP, SIP, and XML traffic) to their networks, security administrators need to stay on their toes and deal with these new protocols by implementing newer tools and technology. One recent example of new technology is the application-level firewall for connecting outside vendors to intranets (also known as an XML firewall, placed within a DMZ) that protects the intranet from malformed XML and SOAP message exploits coming from outside sourced applications.[27]

In conclusion, we can say that with the myriad security issues facing intranets today, most IT shops are still well equipped to defend themselves if they assess risks and, most important, train their employees regarding data security practices on an ongoing basis. The problems with threat mitigation remain largely a matter of meeting gaps in procedural controls rather than technical measures. Trained and security-aware employees are the biggest deterrent to data thefts and security breaches.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

27. Latest standard (version 1.1) for SOAP message security standard from OASIS, a consortium for Web Services Security, www.oasisopen.org/committees/download.php/16790/wss-v1.1-spec-os-SOAPMessageSecurity.pdf.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? In the corporate context, microblogging entails sending short SMS messages to apprise colleagues of recent developments in the daily routine.
2. True or False? Popular devices like the iPad, Samsung Galaxy Android tablet, and many types of smartphones are already capable of accessing company intranets using customized intranet apps.
3. True or False? Quite a few risks need to be resolved when approaching intranet security concerning mobile devices.
4. True or False? Mobile devices accessing enterprise intranets using VPNs have to be subject to the same factors as any other device remotely accessing VPNs.
5. True or False? While there are few risks in deploying mobile devices within the Intranet, with careful configuration these risks can be increased to the point where the myriad benefits outweigh the risks.

Multiple Choice

1. The intranet, as just a simple place to share files and to list a few policies and procedures, has ceased to be. The types of changes can be summed up in the following list of features, which shows that the intranet has become a combined portal as well as a public dashboard. Some of the features include the following, except which one?
   - **A.** A corporate personnel directory of phone numbers by department.
   - **B.** Several RSS feeds for news according to divisions such as IT, HR, Finance, Accounting, and Purchasing.
   - **C.** A search engine for searching company information, often helped by a search appliance from Google.
   - **D.** A section describing company financials and other mission-critical indicators.
   - **E.** A "live" section with IT alerts regarding specific downtimes, outages, and other critical time-sensitive company notifications.
2. Intranet security policies and procedures (P&Ps) are:
   - **A.** The functionality and ease of use of using voice, gesture, and touch interfaces
   - **B.** The first step toward a legal regulatory framework
   - **C.** The availability of customized apps (applications)
   - **D.** The change in the very concept of "being at work" compared to even 10 years ago
   - **E.** The more rapid iteration life cycles of mobile devices

3. The millennial generation is more familiar with:
   - **A.** PCs and laptops.
   - **B.** social media.
   - **C.** mobile technology.
   - **D.** mobile hardware industry.
   - **E.** cloud.
4. Backend enterprise network infrastructure support has to be ready and has to be strong to handle mobile devices interacting with:
   - **A.** iPads.
   - **B.** IPSec.
   - **C.** L2TP VPNs.
   - **D.** SSL VPNs.
   - **E.** PPTP VPNs.
5. What policy/procedure must be signed by new hires at orientation and by all employees who ask for access to the corporate VPN using mobile devices (even personal ones)?
   - **A.** WPA2 encryption for Wi-Fi traffic access
   - **B.** Inbound and outbound malware scanning
   - **C.** A well-tested SSL VPN for remote access
   - **D.** A policy for reporting theft or misplacement
   - **E.** A customized corporate usage policy for mobile devices

How would an organization go about handling the misuse of user privileges on an intranet?

Local Area Network Security

Dr. Pramod Pandya
California State University

Securing available resources on any corporate or academic data network is of paramount importance because most of these networks connect to the Internet for commercial or research activities. Therefore, the network is under attack from hackers on a continual basis, so network security technologies are ever evolving and playing catch-up with hackers. Around 29 years ago the number of potential users was small and the scope of any activity on the network was limited to local networks only. As the Internet expanded in its reach across national boundaries and as the number of users increased, potential risk to the network grew exponentially. Over the past 18 years ecommerce-related activities such as online shopping, banking, stock trading, and social networking have permeated extensively, creating a dilemma for both service providers and their potential clients, as to who is a trusted service provider and a trusted client on the network. Of course, this being a daunting task for security professionals, they have needed to design security policies appropriate for both the servers and their clients. The security policy must be a factor in clients' level of access to the resources. So, in whom do we place trust, and how much trust? Current network designs implement three levels of trust: most trusted, less trusted, and least trusted. Figure 14.1 reflects these levels of trust, as described here:

- The most trusted users belong to the *intranet*. These users have to authenticate to a centralize administrator to access the resources on the network.
- The less trusted users may originate from the intranet as well as the external users who are authenticated to access resources such as email and Web services.
- The least trusted users are the unauthenticated users; most of them are simply browsing the resources on the Internet with no malice intended. Of course, some are scanning the resources with the intent to break in and steal data.

These are the objectives of network security:

- *Confidentiality*. Only authorized users have access to the network.

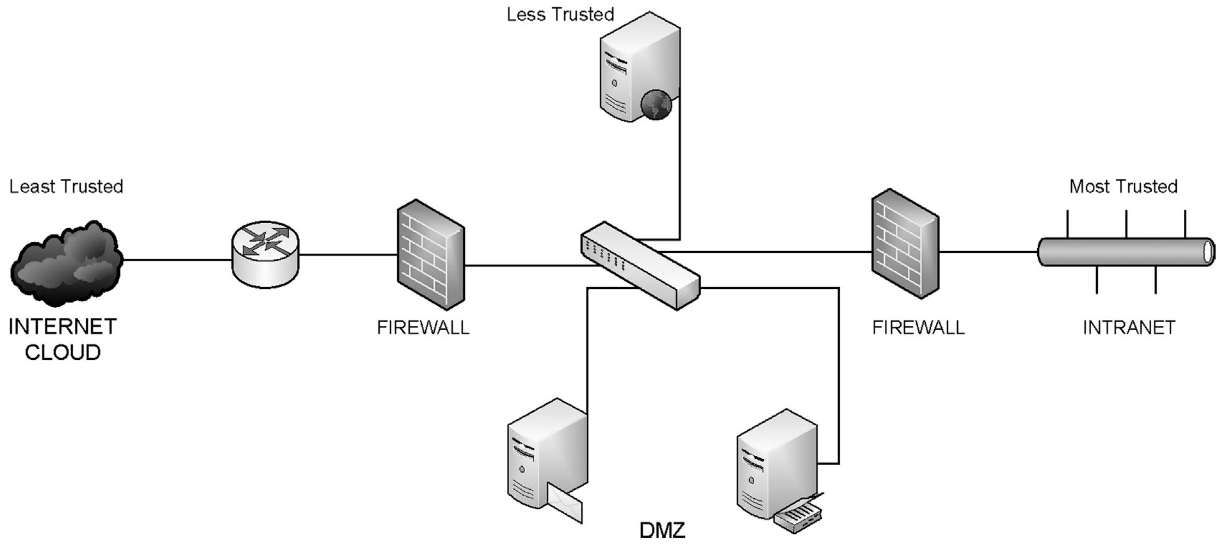

FIGURE 14.1 The DMZ.

- *Integrity.* Data cannot be modified by unauthorized users.
- *Access.* Security must be designed so that authorized users have uninterrupted access to data.

Finally, the responsibility for the design and implementation of network security, is headed by the chief information officer (CIO) of the enterprise network. The CIO has a pool of network administrators and legal advisers to help with this task. The network administrators define the placing of the network access controls, and the legal advisors underline the consequences and liabilities in the event of network security breaches. We have seen cases of customer records such as credit-card numbers, Social Security numbers, and personal information being stolen. The frequency of these reports have been on the increase in the past years, and consequently this has led to a discussion on the merits of encryption of stored data. One of the most quoted legal requirements on the part of any business, whether small or big, is the protection of consumer data under the Health Insurance Portability and Accountability Act (HIPAA), which restricts disclosure of health-related data and personal information.

1. IDENTIFY NETWORK THREATS

Network security threats can be in one of two categories: (1) disruptive type or (2) unauthorized access type.

Disruptive

Most LANs are designed as collapsed backbone networks using a layer-2 or layer-3 switch. If a switch or a router were to fail due to power failure, a segment or the entire network may cease to function until the power is restored. In some case, the network failure may be due to a virus attack on the secondary storage, thus leading to loss of data.

Unauthorized Access

This access type can be internal (employee) or external (intruder), a person who would attempt to break into resources such as database, file, and email or web servers that they have no permission to access. Banks, financial institutions, major corporations, and major retail businesses employ data networks to process customer transactions and store customer information and any other relevant data. Before the birth of the Internet Age, interin-stitutional transactions were secured because the networks were not accessible to intruders or the general public. In the past 14 years, access to the Internet is almost universal; hence institutional data networks have become the target of frequent intruder attacks to steal customer records. One frequently reads in the news about data network security being compromised by hackers, leading to loss of credit card and debit card numbers, Social Security numbers, drivers' license numbers, and other sensitive information such as purchasing profiles. Over the years, although network security has increased, the frequency of attacks on the networks has also increased because the tools to breach the network security have become freely available on the Internet. In 1988 the U.S. Department of Defense established the Computer Emergency Response Team (CERT), whose mission is to work with the Internet community to prevent and respond to computer and network security breaches. Since the Internet is widely used for commercial activities by all kinds of businesses, the federal government has enacted stiffer penalties for hackers.

2. ESTABLISH NETWORK ACCESS CONTROLS

In this part of the chapter, we outline steps necessary to secure networks through network controls. These network controls are either software or hardware based and are implemented in a hierarchical structure to reflect the network organization. This hierarchy is superimposed on the network from the network's perimeter to the access level per user of the network resources. The functions of the network control are to detect an unauthorized access, to prevent network security from being breached, and finally, to respond to a breach—thus the three categories of detect, prevent, and respond.

The role of prevention control is to stop unauthorized access to any resource available on the network. This could be implemented as simply as a password required to authenticate the user to access the resource on the network. For an authorized user this password can grant login to the network to access the services of a database, file, Web, print, or email server. The network administrator would need a password to access the switch or a router. The prevention control in this case is software based. An analog of hardware-based control would be, for example, if the resources such as server computers, switches, and routers are locked in a network access control room.

The role of the detection control is to monitor the activities on the network and identify an event or a set of events that could breach network security. Such an event may be a virus, spyware, or adware attack. The detection control software must, besides registering the attack, generate or trigger an alarm to notify of an unusual event so that a corrective action can be taken immediately, without compromising security.

TABLE 14.1 Mission-Critical Components of any Enterprise Network.

	Threats					
Resources	**Fire, Flood, Earthquake**	**Power Failure**	**Spam**	**Virus**	**Spyware, Adware**	**Hijacking**
Perimeter Router						
DNS Server						
WEB Server						
Email Server						
Core Switches						
Databases						

The role of the response control is to take corrective action whenever network security is breached so that the same kind of breach is detected and any further damage is prevented.

3. RISK ASSESSMENT

During the initial design phase of a network, the network architects assess the types of risks to the network as well as the costs of recovering from attacks for all the resources that have been compromised. These cost factors can be realized using well-established accounting procedures such as cost/benefit analysis, return on investment (ROI), and total cost of ownership (TCO). These risks could range from natural disaster to an attack by a hacker. Therefore, you need to develop levels of risks to various threats to the network. You need to design some sort of spreadsheet that lists risks versus threats as well as responses to those identified threats. Of course, the spreadsheet would also mark the placing of the network access controls to secure the network.

4. LISTING NETWORK RESOURCES

We need to identify the assets (resources) that are available on the corporate network. Of course, this list could be long, and it would make no sense to protect all the resources, except for those that are mission-critical to the business functions. Table 14.1 identifies mission-critical components of any enterprise network. You will observe that these mission-critical components need to be prioritized, since they do not all provide the same functions. Some resources provide controlled access to a network; other resources carry sensitive corporate data. Hence the threats posed to these resources do not carry the same degree of vulnerabilities to the network. Therefore, the network access control has to be articulated and applied to each of the components listed, in varying degrees. For example, threats to DNS server pose a different set of problems from threats to the database servers. Next, we itemize the threats to these resources and specific network access controls.

5. THREATS

We need to identify the threats posed to the network from internal users as opposed to those from external users. The reason for such a distinction is that the internal users are easily traceable, compared to the external users. If a threat to the data network is successful, and it could lead to loss or theft of data or denial of access to the services offered by the network, it would lead to monetary loss for the corporation. Once we have identified these threats, we can rank them from most probable to least probable and design network security policy to reflect that ranking.

From Table 14.2, we observe that most frequent threats to the network are from viruses, and we have seen a rapid explosion in antivirus, antispamware, and spyware and adware software. Hijacking of resources such as domain name services, Web services, and perimeter routers would lead to what's most famously known as denial of service (DoS) or distributed denial of service (DDoS). Power failures can always be complemented by standby power supplies that could keep the essential resources from crashing. Natural disasters such as fire, floods, or earthquakes can be most difficult to plan for; therefore we see a tremendous growth in data protection and backup service provider businesses.

6. SECURITY POLICIES

The fundamental goals of security policy are to allow uninterrupted access to the network resources for authenticated users and to deny access to unauthenticated users. Of course, this is always a balancing act between the users' demands on network resources and the

TABLE 14.2 The Most Frequent Threats to the Network Are from Viruses.

Rank	Threat
1	Virus
2	Spam
3	Spyware, Adware
4	Hijacking
5	Power Failure
6	Fire, Flood, Earthquake

evolutionary nature of information technology. The user community would prefer open access, whereas the network administrator insists on restricted and monitored access to the network.

The hacker is, in the final analysis, the arbitrator of the network security policy, since it is always the unauthorized user who discovers the potential flaw in the software. Hence, any network is as secure as the last attack that breached its security. It would be totally unrealistic to expect a secured network at all times, once it is built and secured. Therefore, network security design and its implementation represent the ultimate battle of the minds between the chief information security officer (CISO) and the devil, the hacker. We can summarize that the network security policy can be as simple as to allow access to resources, or it can be several hundred pages long, detailing the levels of access and punishment if a breach is discovered. Most corporate network users now have to sign onto the usage policy of the network and are reminded that security breaches are a punishable offence. The critical functions of a good security policy are:

- Appoint a security administrator who is conversant with users' demands and on a continual basis is prepared to accommodate the user community's needs.
- Set up a hierarchical security policy to reflect the corporate structure.
- Define ethical Internet access capabilities.
- Evolve the remote access policy.
- Provide a set of incident-handling procedures.

7. THE INCIDENT-HANDLING PROCESS

The incident-handling process is the most important task of a security policy for the reason that you would not want to shut down the network in case of a network security breach. The purpose of the network is to share the resources; therefore an efficient procedure must be developed to respond to a breach. If news of the network security breach becomes public, the corporation's business practices could become compromised, thus resulting in compromise of its business operations. Therefore set procedures must be developed jointly with the business operations manager and the chief information officer. This calls for a modular design of the enterprise network so that its segments can be shut down in an orderly way, without causing panic.

Toward this end, we need a set of tools to monitor activities on the network—we need an intrusion detection and prevention system. These pieces of software will monitor network activities and log and report an activity that does not conform to usual or acceptable standards as defined by the software. Once an activity is detected and logged, response is activated. It is not merely sufficient to respond to an incident; the network administrator also has to activate tools to trace back to the source of this breach. This is critical so that the network administrator can update the security procedures to make sure that this particular incident does not take place.

8. SECURE DESIGN THROUGH NETWORK ACCESS CONTROLS

A network is as secure as its weakest link in the overall design. To secure it, we need to identify the entry and exit points into the network. Since most data networks have computational nodes to process data and storage nodes to store data, stored data may need to be encrypted so that if network security is breached, stolen data may still remain confidential unless the encryption is broken. As we hear of cases of stolen data from either hacked networks or stolen nodes, encrypting data while it's being stored appears to be necessary to secure data.

The entry point to any network is a perimeter router, which sits between the external firewall and the Internet; this model is applicable to most enterprise networks that engage in some sort of ecommerce activities. Hence our first network access control is to define security policy on the perimeter router by configuring the appropriate parameters on the router. The perimeter router will filter traffic based on the range of IP addresses.

Next in the line of defense is the external firewall that filters traffic based on the state of the network connection. Additionally, the firewall could also check the contents of the traffic packet against the nature of the Transmission Control Protocol (TCP) connection requested. Following the firewall we have the so-called demilitarized zone, or DMZ, where we would place the following servers: Web, DNS, and email. We could harden these servers so that potential threatening traffic can be identified and appropriate incident response generated.

The DMZ is placed between two firewalls, so our last line of defense is the next firewall that would inspect the traffic and possibly filter out the potential threat. The nodes that are placed on the intranet can be protected by commercially available antivirus software. Last but not least, we could install on the network an intrusion detection and prevention system that will generate real-time response to a threat.

Next we address each of the network control access points. The traditional network design includes an access layer, a distribution layer, and the core layer. In the case of a local area network (LAN) we will use the access and distribution layers; the core layer would simply be our perimeter router that we discussed earlier. Thus the LAN will consist of a number of segments reflecting the organizational structure. The segments could sit behind their firewall to protect one another as well, in case of network breach; segments under attack can be isolated, thus preventing a cascade-style attack on the network.

9. IDS DEFINED

An intrusion detection system, or IDS, can be both software and hardware based. IDSs listen to all the activities taking place on both the computer (node on a network) and the network itself. One could think of an IDS as like traffic police, whose function is to monitor the data packet traffic and detect and identify those data packets that match predefined unusual pattern of activities. An IDS can also be programmed to teach itself from its past activities to refine the rules for unusual activities. This should not come as a surprise, since the hackers also get smarter over time.

As we stated, the IDS collects information from a variety of system and network resources, but in actuality it captures packets of data as defined by the TCP/IP protocol stack. In this sense IDS is both a sniffer and analyzer software. IDS in its sniffer role would either capture all the data packets or select ones as specified by the configuration script. This configuration script is a set of rules that tell the analyzer what to look for in a captured data packet, then make an educated guess per rules and generate an alert. Of course, this could lead to four possible outcomes with regard to intrusion detection: false positive, false negative, true positive, or true negative. We address this topic in more detail later in the chapter. IDSs performs a variety of functions:

- Monitor and analyze user and system activities
- Verify the integrity of data files
- Audit system configuration files
- Recognize activity of patterns, reflecting known attacks
- Statistical analysis of any undefined activity pattern

An IDS is capable of distinguishing different types of network traffic, such as an HTTP request over port 80 from some other application such as SMTP being run over port 80. We see here that an IDS understands which TCP/IP applications run over which preassigned port numbers, and therefore falsifying port numbers would be trivially detectable. This is a very easy illustration, but there are more complex attacks that are not that easy to identify, and we shall cover them later in this chapter.

The objective of intrusion detection software packages is to make possible the complex and sometimes virtually impossible task of managing system security. With this in mind, it might be worthwhile to bring to our attention two industrial-grade IDS software packages: Snort (NIDS), which runs on both Linux and Windows, and GFI LANguard S.E.L.M., a host intrusion detection system (HIDS), which runs on Windows only. Commercial-grade IDS software is designed with user-friendly interfaces that make it easy to configure scripts, which lay down the rules for intrusion detection. Next let's examine some critical functions of an IDS:

- Can impose a greater degree of flexibility to the security infrastructure of the network
- Monitors the functionality of routers, including firewalls, key servers, and critical switches
- Can help resolve audit trails, thus often exposing problems before they lead to loss of data
- Can trace user activity from the network point of entry to the point of exit
- Can report on file integrity checks
- Can detect whether a system has been reconfigured by an attack
- Can recognize a potential attack and generate an alert
- Can make possible security management of a network by nonexpert staff

10. NIDS: SCOPE AND LIMITATIONS

Network-based IDS (NIDS) sensors scan network packets at the router or host level, auditing data packets and logging any suspicious packets to a log file. Figure 14.2 is an example of a NIDS. The data packets are captured by a sniffer program, which is a part of the IDS software package. The node on which the IDS software is enabled runs in promiscuous mode. In promiscuous mode, the NIDS node captures all the data packets on the network as defined by the configuration script. NIDSs have become a critical component of network security management as the number of nodes on the Internet has grown exponentially over last few years. Some of the common malicious attacks on networks are:

- IP address spoofing
- MAC address spoofing
- ARP cache poisoning
- DNS name corruption

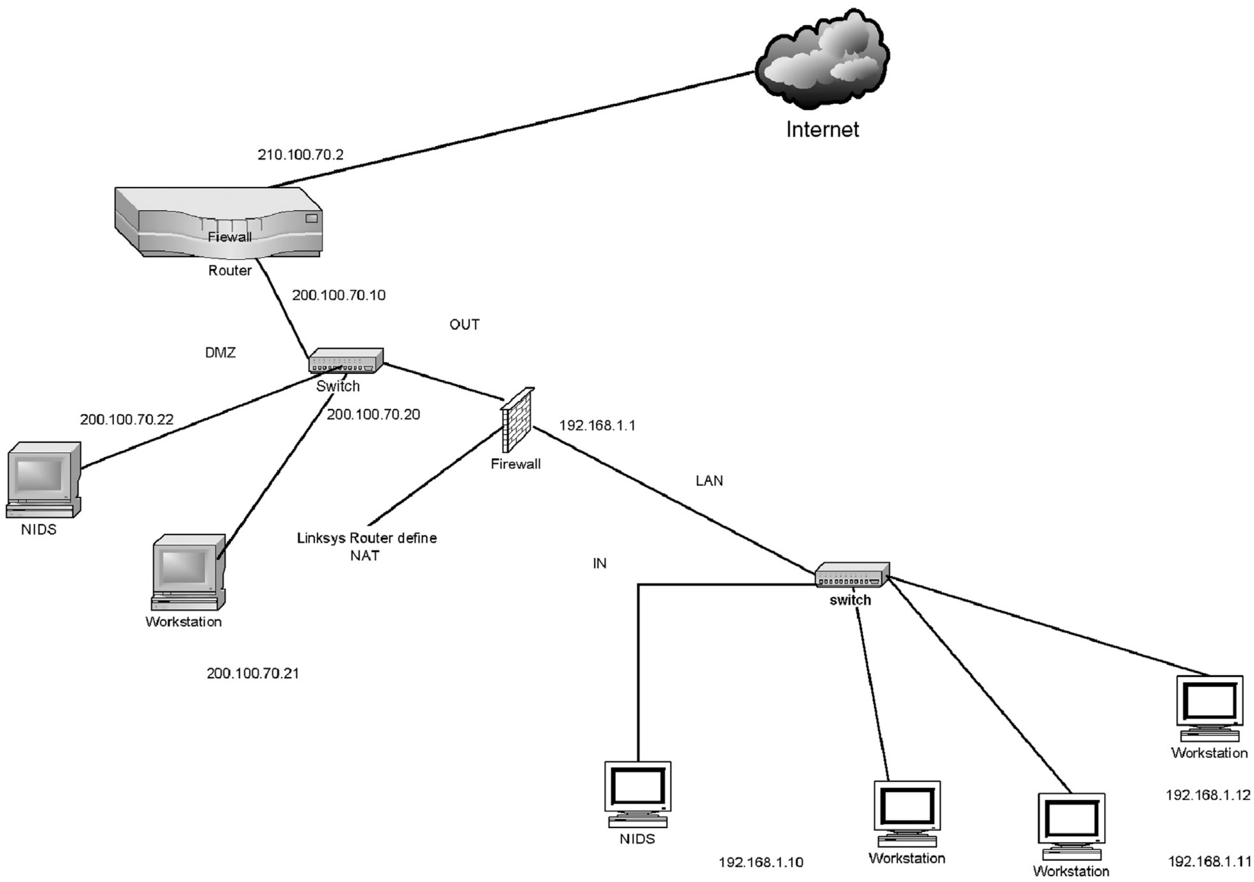

FIGURE 14.2 An example of a network-based intrusion detection system.

11. A PRACTICAL ILLUSTRATION OF NIDS

In this part of the chapter, we illustrate the use of Snort as an example of a NIDS. The signature files are kept in the directory signatures under the directory .doc. Signature files are used to match defined signature against a pattern of bytes in the data packets, to identify a potential attack. Files marked as rules in the rules directory are used to trigger an alarm and write to the file alert.ids. Snort is installed on a node with IP address 192.168.1.22. The security auditing software Nmap is installed on a node with IP address 192.168.1.20. Nmap software is capable of generating ping sweeps, TCP SYN (half-open) scanning, TCP connect() scanning, and much more. Figure 14.2 has a node labeled *NIDS* (behind the Linksys router) on which Snort would be installed. One of the workstations would run Nmap software.

UDP Attacks

A UDP attack is generated from a node with IP address 192.168.1.20 to a node with IP address 192.168.1.22. Snort is used to detect a possible attack. Snort's detect engine uses one of the files in DOS under directory rules to generate the alert file alert.ids. We display a partial listing (see Listing 14.1) of the alert.ids file.

Listing 14.2 shows a partial listing of DOS rules file. The rules stated in the DOS rules file are used to generate the alert.ids file.

TCP SYN (Half-Open) Scanning

This technique is often referred to as *half-open* scanning because you don't open a full TCP connection. You send a SYN packet, as though you were going to open a real connection, and wait for a response. A SYN|ACK indicates that the port is listening. An RST is indicative of a nonlistener. If a SYN|ACK is received, you immediately send an RST to tear down the connection (actually, the kernel does this for you). The primary advantage of this scanning technique is that fewer sites will log it! SYN scanning is the *-s* option of Nmap.

A SYN attack is generated using Nmap software from a node with IP address 192.168.1.20 to a node with IP address 192.168.1.22. Snort is used to detect for a

possible attack. Snort's detect engine uses scan and ICMP rules files under directory rules to generate the alert file alert.ids. A partial listing of alert.ids file is shown in Listing 14.3.

A partial listing of the scan rules appears in Listing 14.4. Listing 14.5 contains a partial listing of the ICMP rules. The following points must be noted about NIDS:

- One NIDS is installed per LAN (Ethernet) segment.
- Place NIDS on the auxiliary port on the switch and then link all the ports on the switch to that auxiliary port.
- When the network is saturated with traffic, the NIDS might drop packets and thus create a potential "hole."
- If the data packets are encrypted, the usefulness of an IDS is questionable.

Some Not-So-Robust Features of NIDS

Network security is a complex issue with myriad possibilities and difficulties. In networks, security is also a weakest link phenomenon, since it takes vulnerability on one node to allow a hacker to gain access to a network and thus create chaos on the network. Therefore IDS products are vulnerable.

An IDS cannot compensate for weak identification and authentication. Hence you must rely on other means of identification and authentication of users. This is best implemented by token-based or biometric schemes and one-time passwords.

An IDS cannot conduct investigations of attacks without human intervention. Therefore when an incident does occur, steps must be defined to handle the incident. The incident must be followed up to determine the responsible party, then the vulnerability that allowed the problem to occur should be diagnosed and corrected. You will observe that an IDS is not capable of identifying the attacker, only the IP address of the node that served as the hacker's point of entry.

An IDS cannot compensate for weaknesses in network protocols. IP and MAC address spoofing is a very common form of attack in which the source IP or MAC address does not correspond to the real source IP or MAC

LISTING 14.2 The DOS rules file.

address of the hacker. Spoofed addresses can be mimicked to generate DDoS attacks.

An IDS cannot compensate for problems in the integrity of information the system provides. Many hacker tools target system logs, selectively erasing records corresponding to the time of the attack and thus covering the hacker's tracks. This calls for redundant information sources.

An IDS cannot analyze all the traffic on a busy network. A network-based IDS in promiscuous mode, can capture all of the data packets; and, as the traffic level raises, NIDS can reach a saturation point and begin to lose data packets.

An IDS cannot always deal with problems involving packet-level attacks. The vulnerabilities lie in the difference between IDS interpretation of the outcome of a network transaction and the destination node for that network session's actual handling of the transaction. Therefore, a hacker can send a series of fragmented network transactions.

Packets that elude detection and can also launch attacks on the destination node. Even worse, the hacker can lead to DoS on the IDS itself.

An IDS has problems dealing with fragmented data packets. Hackers would normally use fragmentation to confuse the IDS and thus launch an attack.

12. FIREWALLS

A firewall is either a single node or a set of nodes that enforce an access policy between two networks. Firewall technology evolved to protect the intranet from unauthorized users on the Internet. This was the case in the earlier years of corporate networks. Since then, the network administrators have realized that networks can also be attacked from trusted users as well as, for example, the employee of a company. The corporate network consists of hundreds of nodes per department and thus aggregates to over a thousand or more, and now there is a need to protect data in each department from other departments. Hence, a need for internal firewalls arose to protect data from unauthorized access, even if they are employees of the corporation. This need has, over the years, led to design of segmented IP networks, such that internal firewalls would form barriers within barriers, to restrict a potential break-in to an IP segment rather than expose the entire corporate network to a hacker. For this reason, network security has grown into a multibillion-dollar business.

Almost every intranet, whether of one node or many nodes, is always connected to the Internet, and thus a potential number of hackers wait to attack it. Thus every intranet is an IP network, with TCP- and UDP-based

LISTING 14.3 Alert.ids file.

applications running over it. The design of TCP and UDP protocols require that every client/server application interacts with other client/server applications through TCP and UDP port numbers. As we stated earlier, these TCP and UDP port numbers are well known and hence give rise to a necessary weakness in the network. TCP and UDP port numbers open up "holes" in the networks by their very design. Every Internet and intranet point of entry has to be guarded, and you must monitor the traffic (data packets) that enter and leave the network.

A firewall is a combination of hardware and software technology, namely a sort of sentry, waiting at the points of entry and exit to look out for an unauthorized data packet trying to gain access to the network. The network administrator, with the help of other IT staff, must first identify the resources and the sensitive data that need to be protected from the hackers. Once this task has been accomplished, the next task is to identify who would have access to these identified resources and the data. We should pointed out that most of the networks in any corporation are never designed and built from scratch but are added to an existing network as the demand for networking grows with the growth of the business. So, the design of the network security policy has multilayered facets as well.

Once the network security policy is defined and understood, we can identify the proper placement of the firewalls in relation to the resources on the network. Hence, the next step would be to actually place the firewalls in the network as nodes. The network security policy now defines access to the network, as implemented in the firewall. These access rights to the network resources are based on the characteristics of TCP/IP protocols and the TCP/UDP port numbers.

Firewall Security Policy

The firewall enables the network administrator to centralize access control to the campuswide network. A firewall logs every packet that enters and leaves the

network. The network security policy implemented in the firewall provides several types of protection, including the following:

- Block unwanted traffic
- Direct incoming traffic to more trustworthy internal nodes
- Hide vulnerable nodes that cannot easily be secured from external threats
- Log traffic to and from the network

A firewall is transparent to authorized users (both internal and external), whereas it is not transparent to unauthorized users. However, if the authorized user attempts to access a service that is not permitted to that user, a denial of that service will be echoed, and that attempt will be logged.

Firewalls can be configured in a number of architectures, providing various levels of security at different costs of installation and operations. Figure 14.2 is an example of a design termed a *screened Subnet*. In this design, the internal network is a private IP network, so the resources on that network are completely hidden from the users who are external to that network, such as users from the Internet. In an earlier chapter we talked about public versus private IP addresses. It is agreed to by the IP community that nodes with private IP addresses will not be accessible from outside that network. Any number of corporations may use the same private IP network

address without creating packets with duplicated IP addresses. This feature of IP networks, namely private IP networks, adds to network security. In Figure 14.2, we used a Linksys router to support a private IP network (192.168.1.0) implementation. For the nodes on the 192.168.1.0 network to access the resources on the Internet, the Linksys router has to translate the private IP address of the data packet to a public IP address. In our scenario, the Linksys router would map the address of the node on the 192.168.1.0 network, to an address on the public network, 200.100.70.0. This feature is known as Network Address Translation (NAT), which is enabled on the Linksys router. You can see in Figure 14.2 that the Linksys router demarks the internal (IN) network from the external (OUT) network.

We illustrate an example of network address translation, as shown in Listing 14.6. The script configures a Cisco router that translates an internal private IP address

```

LISTING 14.6 Network Address Translation (NAT).

to a public IP address. Of course, configuring a Linksys router is much simpler using a Web client. An explanation of the commands and their details follow the script.

Configuration Script for sf Router

The access-list command creates an entry in a standard traffic filter list:

- Access-list "access-list-number" permit|deny source [source-mask]
- Access-list number: identifies the list to which the entry belongs; a number from 1 to 99
- Permit|deny: this entry allows or blocks traffic from the specified address
- Source: identifies source IP address
- Source-mask: identifies the bits in the address field that are matched; it has a 1 in position indicating "don't care" bits, and a 0 in any position that is to be strictly followed

The IP access-group command links an existing access list to an outbound interface. Only one access list per port, per protocol, and per direction is allowed.

- Access-list-number: indicates the number of the access list to be linked to this interface
- In|out: selects whether the access list is applied to the incoming or outgoing interface; out is the default

NAT is a feature that operates on a border router between an inside private addressing scheme and an outside public addressing scheme. The inside private address is 192.168.1.0 and the outside public address is chosen to be 200.100.70.0. Equivalently, we have an intranet on the inside and the Internet on the outside.

13. DYNAMIC NAT CONFIGURATION

First a NAT pool is configured from which outside addresses are allocated to the requesting inside hosts: IP NAT pool "pool name" "start outside IP address" "finish outside IP address." Next the access-list is defined to determine which inside networks are translated by the NAT router: access-list "unique access-list number" permit|deny "inside IP network address." Finally the NAT pool and the access list are correlated:

- IP NAT inside source list "unique access list number" pool "pool name"
- Enable the NAT on each interface of the NAT router
- IP NAT inside+ + + + + + + + + + + + + + + + IP NAT outside

You will note that only one interface may be configured as outside, yet multiple interfaces may be configured as inside, with regard to Static NAT configuration:

- IP NAT inside source static "inside IP address" "outside IP address"
- IP NAT inside source static 192.168.1.100 200.100.70.99

14. THE PERIMETER

In Figure 14.3, you will see yet another IP network labeled *demilitarized zone* (DMZ). You may ask, why yet another network? The rationale behind this design is as follows.

The users that belong to IN might want to access the resources on the Internet, such as read their email and send email to the users on the Internet. The corporation needs to advertise its products on the Internet.

The DMZ is the perimeter network, where resources have public IP addresses, so they are seen and heard on the Internet. The resources such as the Web (HTTP), email (SMTP), and domain name server (DNS) are placed in the DMZ, whereas the rest of the resources that belong to this corporation are completely hidden behind the Linksys router. The resources in the DMZ can be attacked by the hacker because they are open to users on the Internet. The relevant TCP and UDP port numbers on the servers in the DMZ have to be left open to the incoming

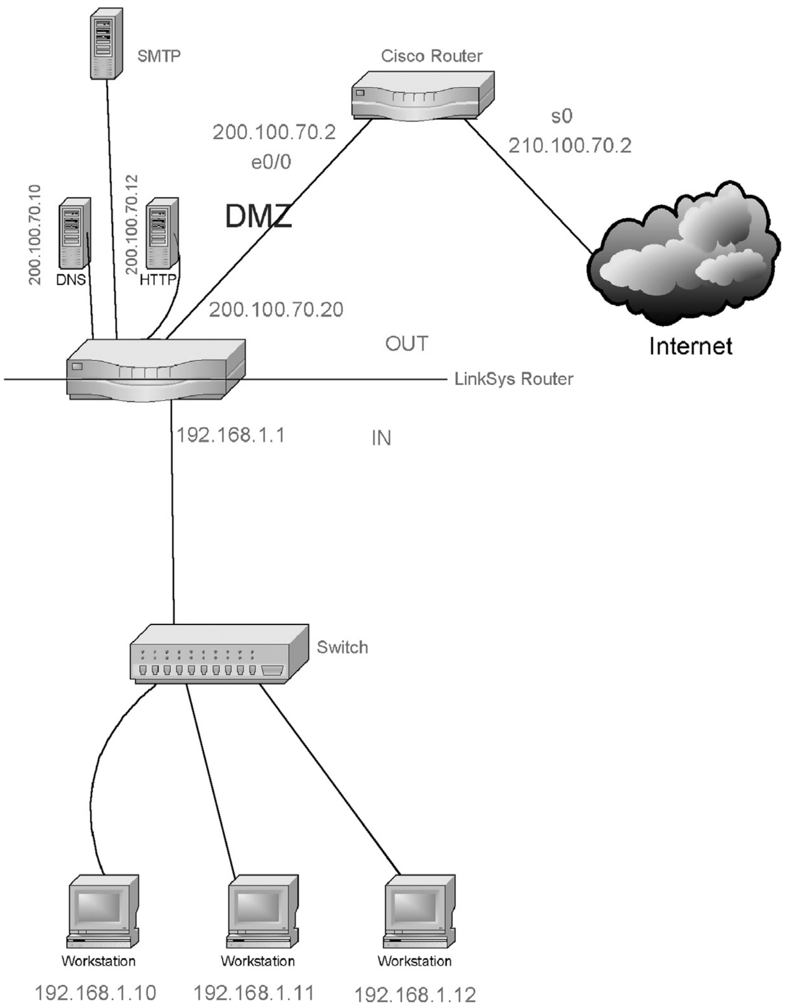

FIGURE 14.3 An illustrative firewall design.

and outgoing traffic. Does this create a potential "hole" in the corporate network? The answer to this is both yes and no. Someone can compromise the resources in the DMZ without the entire network being exposed to a potential attack.

The first firewall is the Cisco router, and it is the first line of defense, were network security policy implemented. On the Cisco router it is known as the Access Control List (ACL). This firewall will allow external traffic to inbound TCP port 80 on the Web server, TCP port 25 on the email server, and TCP and UDP port 53 on the DNS server. The external traffic to the rest of the ports will be denied and logged.

The second line of defense is the Linksys router that will have well-known ports closed to external traffic. It too will monitor and log the traffic. It is acceptable to place email and the Web server behind the Linksys router on the private IP network address. Then you will have to open up the TCP ports 80 and 25 on the Linksys router so that the external traffic can be mapped to ports 80 and 25, respectively. This would slow down the traffic because the Linksys router (or any commercial-grade router) would have to constantly map the port numbers back and forth. Finally, the DNS server would always need to be placed in the DMZ with a public IP address, since it will be used to resolve domain names by both internal and external users. This decision has to be left to the corporate IT staff.

15. ACCESS LIST DETAILS

The Cisco router in Figure 14.3 can be configured with the following access list to define network security policy. Building an access list in the configuration script of the router does not activate the list unless it is applied to an interface. "ip access-group 101 in" applies the access-list 101 to the serial interface of the router. Some of the access-list commands are explained here. For more

information on Cisco access-list commands, visit the Cisco Web site (www.cisco.com):

- ip access-group group no. {in|out}: default is out
- What is the group number?
- The group number is the number that appears in the access-list command line
- What is {in|out}?
- In implies that the packet enters the router's interface from the network
- Out implies that the packet leaves the router's interface to the network

All TCP packets are IP packets, but all IP packets are not TCP packets. Therefore, entries matching on IP packets are more generic than matching on TCP, UDP, or ICMP packets. Each entry in the access list is interpreted (see Listing 14.7) from top to bottom for each packet on the specified interface. Once a match is reached, the remaining access-list entries are ignored. Hence, the order of entries in an access list is very critical, and therefore more specific entries should appear earlier on.

This permits TCP from any host to any host if the ACK or RST bit is set, which indicates that it is part of an established connection. You will note that in a TCP Full Connect, the first packet from the source node does not have the ACK bit set. The keyword *established* is meant to prevent an untrusted user from initiating a connection while allowing packets that are part of already established TCP connections to go through:

- Access-list 101 permit udp any gt 1023 host 200.100.70.10 eq 53
- Permit UDP protocol from any host with port greater than 1023 to the DNS server at port 53
- Access-list 101 permit ip any host 200.100.70.12
- Permit IP from any host to 200.100.70.12

or

- Access-list 101 permit TCP any 200.100.70.12 eq 80
- Permit any host to engage with our HTTP server on port 80 only
- Access-list 101 permit icmp any echo-reply
- Permit ICMP from any host to any host if the packet is in response to a ping request
- Access-list 101 deny ip any any

```
interface serial0
ip address 210.100.70.2
ip access-group 101 in
!
access-list 101 permit tcp any any established
```

LISTING 14.7 Access-list configuration script.

The last access-list command is implicit (that is, not explicitly stated). The action of this last access-list is to deny all other packets.

16. TYPES OF FIREWALLS

Conceptually, there are three types of firewalls:

- *Packet filtering*. Permit packets to enter or leave the network through the interface on the router on the basis of protocol, IP address, and port numbers.
- *Application-layer firewall.* A proxy server that acts as an intermediate host between the source and the destination nodes.
- *Stateful-inspection layer.* Validates the packet on the basis of its content.

17. PACKET FILTERING: IP FILTERING ROUTERS

An IP packet-filtering router permits or denies the packet to either enter or leave the network through the interface (incoming and outgoing) on the basis of the protocol, IP address, and the port number. The protocol may be TCP, UDP, HTTP, SMTP, or FTP. The IP address under consideration would be both the source and the destination addresses of the nodes. The port numbers would correspond to the well-known port numbers. The packet-filtering firewall has to examine every packet and make a decision on the basis of defined ACL; additionally it will log the following guarded attacks on the network:

- A hacker will attempt to send IP spoofed packets using raw sockets (we will discuss more about usage of raw sockets in the next chapters)
- Log attempted network scanning for open TCP and UDP ports—NIDS will carry out this detective work in more detail
- SYN attacks using TCP connect(), and TCP half open
- Fragment attacks

18. APPLICATION-LAYER FIREWALLS: PROXY SERVERS

These are proxy servers that act as an intermediary host between the source and the destination nodes. Each of the sources would have to set up a session with the proxy server, then the proxy server would set up a session with the destination node. The packets would have to flow through the proxy server. There are examples of Web and FTP proxy servers on the Internet. The proxy servers would also have to be used by the internal users, that is, the traffic from the internal users will have to run through the proxy server to the outside network. Of course, this

slows the flow of packets, but you must pay the price for added network security.

19. STATEFUL INSPECTION FIREWALLS

In here the firewall will examine the contents of the packets before permitting them to either enter or leave the network. The contents of the packets must conform with the protocol declared with the packet. For example, if the protocol declared is HTTP, the contents of the packet must be consistent with the HTTP packet definition.

20. NIDS COMPLEMENTS FIREWALLS

A firewall acts as a barrier, if so designed, among various IP network segments. Firewalls may be defined among IP intranet segments to protect resources. In any corporate network, there will always be more than one firewall because an intruder could be one of the authorized network users. Hence the following points should be noted:

- Not all threats originate outside the firewall.
- The most trusted users are also the potential intruders.
- Firewalls themselves may be subject to attack.

Since the firewall sits at the boundary of the IP network segments, it can only monitor the traffic entering and leaving the interface on the firewall that connects to the network. If the intruder is internal to the firewall, the firewall will not be able to detect the security breach. Once an intruder has managed to transit through the interface of the firewall, the intruder would go undetected, which could possibly lead to stealing sensitive information, destroying information, leaving behind viruses, staging attacks on other networks, and most important, leaving spyware software to monitor the activities on the network for future attacks. Hence, a NIDS would play a critical role in monitoring activities on the network and continually looking for possible anomalous patterns of activities.

Firewall technology has been around for the past 25 years, so much has been documented about its weaknesses and strengths. Information about firewalls is freely available on the Internet. Hence a new breed of hackers have utilized *tunneling* as a means of bypassing firewall security policy. NIDS enhances security infrastructure by monitoring system activities for signs of attack and then, based on the system settings, responds to the attack as well as generates an alarm. Response to a potential attack is known as the *incident response* or *incident handling*, which combines investigation and diagnosis phases. Incident response has been an emerging technology in the past 7 years and is now an integral part of intrusion detection and prevention technology.

Finally, but not least, securing network systems is an ongoing process in which new threats arise all the time. Consequently, firewalls, NIDS, and intrusion prevention systems are continuously evolving technologies. In this chapter and subsequent chapters our focus has been and will be wired networks. However, as wireless data networks proliferate and seamlessly connect to the cellular voice networks, the risk of attacks on the wired networks is growing exponentially.

21. MONITOR AND ANALYZE SYSTEM ACTIVITIES

Figure 14.1 shows the placement of a NIDS, one in the DMZ and the other in the private network. This suggests at least two points on the network from which we capture data packets. The next question is the timing of the information collection, although this depends on the degree of threat perceived to the network.

If the level of perceived threat to the network is low, an immediate response to the attack is not very critical. In such a case, interval-oriented data capturing and analysis is most economical in terms of load placed on a NIDS and other resources on the network. Additionally, there might not be full-time network security personnel to respond to an alarm triggered by the NIDS.

If the level of perceived threat is imminent and the time and the data are mission-critical to the organization, real-time data gathering and analysis are of extreme importance. Of course, the real-time data gathering would impact the CPU cycles on the NIDS and would lead to a massive amount of data storage. With real-time data capturing and analysis, real-time response to an attack can be automated with notification. In such a case, network activities can be interrupted, the incident could be isolated, and system and network recovery could be set in motion.

Analysis Levels

Capturing and storing data packets are among the manageable functions of any IDS. How do we analyze the data packets that represent potential or imminent threats to the network?

We need to examine the data packets and look for evidence that could point to a threat. Let's examine the makeup of data packets. Of course, any packet is almost encapsulated by successive protocols from the Internet model, with the data as its kernel. Potential attacks could be generated by IP or MAC spoofing, fragmented IP packets leading to some sort of DoS, saturating the resource with flooding, and much more. We should remind readers that since humans are not going to examine the data

packets, this process of examination is relegated to an algorithm. This algorithm must compare the packets with a known format of the packet (signature) that suggests an attack is in progress, or it could be that there is some sort of unusual activity on the network. How does one distinguish abnormal from normal sets of activities? There must be some baseline (statistical) that indicates normal, and deviation from it would be an indicator of abnormal. We explore these concepts in the following paragraphs.

We can identify two levels of analysis: signature and statistical.

22. SIGNATURE ANALYSIS

Signature analysis includes some sort of pattern matching of the contents of the data packets. There are patterns corresponding to known attacks. These known attacks are stored in a database, and a pattern is examined against the known pattern, which defines signature analysis. Most commercial NIDS products perform signature analysis against a database of known attacks, which is part of the NIDS software. Even though the databases of known attacks may be proprietary to the vendor, the client of this software should be able to increase the scope of the NIDS software by adding signatures to the database. Snort is open-source NIDS software, and the database of known attacks is maintained and updated by the user community. This database is an ASCII (human-readable) file.

23. STATISTICAL ANALYSIS

First we have to define what constitutes a normal traffic pattern on the network. Then we must identify deviations away from normal patterns as potential threats. These deviations must be arrived at by statistical analysis of the traffic patterns. A good example would be how many times records are written to a database over a given time interval, and deviations from normally accepted numbers would be an indication of an impending attack. Of course, a clever hacker could mislead the detector into accepting attack activity as normal by gradually varying behavior over time. This would be an example of a false negative.

24. SIGNATURE ALGORITHMS

Signature analysis is based on the following algorithms:

- Pattern matching
- Stateful pattern matching
- Protocol decode-based analysis
- Heuristic-based analysis
- Anomaly-based analysis

Pattern Matching

Pattern matching is based on searching for a fixed sequence of bytes in a single packet. In most cases the pattern is matched against only if the suspect packet is associated with a particular service or, more precisely, destined to and from a particular port. This helps to reduce the number of packets that must get examined and thus speed up the process of detection. However, it tends to make it more difficult for systems to deal with protocols that do not live on well-defined ports.

The structure of a signature based on the simple pattern-matching approach might be as follows: First, the packet is IPv4 or higher and TCP, the destination port is 3333, and the payload contains the fictitious string *psuw*, trigger an alarm. In this example, the pattern *psuw* is what we were searching for, and one of the IDS rules implies to trigger an alarm. One could do a variation on this example to set up more convoluted data packets. The advantage of this simple algorithm is:

- This method allows for direct correlation of an exploit with the pattern; it is highly specific.
- This method is applicable across all protocols.
- This method reliably alerts on the pattern matched.

The disadvantages of this pattern-matching approach are as follows:

- Any modification to the attack can lead to missed events (false negatives).
- This method can lead to high false-positive rates if the pattern is not as unique as the signature writer assumed.
- This method is usually limited to inspection of a single packet and, therefore, does not apply well to the stream-based nature of network traffic such as HTTP traffic. This scenario leads to easily implemented evasion techniques.

Stateful Pattern Matching

This method of signature development adds to the pattern-matching concept because a network stream comprises more than a single atomic packet. Matches should be made in context within the state of the stream. This means that systems that perform this type of signature analysis must consider arrival order of packets in a TCP stream and should handle matching patterns across packet boundaries. This is somewhat similar to a stateful firewall.

Now, instead of looking for the pattern in every packet, the system has to begin to maintain state information on the TCP stream being monitored. To understand

the difference, consider the following scenario. Suppose that the attack you are looking for is launched from a client connecting to a server and you have the pattern-match method deployed on the IDS. If the attack is launched so that in any given single TCP packet bound for the target on port 3333 the string is present, this event triggers the alarm. If, however, the attacker causes the offending string to be sent such that the fictitious *gp* is in the first packet sent to the server and *o* is in the second, the alarm does not get triggered. If the stateful pattern-matching algorithm is deployed instead, the sensor has stored the *gp* portion of the string and is able to complete the match when the client forwards the fictitious *p*. The advantages of this technique are as follows:

- This method allows for direct correlation of an exploit with the pattern.
- This method is applicable across all protocols.
- This method makes evasion slightly more difficult.
- This method reliably alerts on the pattern specified.

The disadvantages of the stateful pattern matching-based analysis are as follows:

- Any modification to the attack can lead to missed events (false negatives).
- This method can lead to high false-positive rates if the pattern is not as unique as the signature writer assumed.

Protocol Decode-based Analysis

In many ways, intelligent extensions to stateful pattern matches are protocol decode-based signatures. This class of signature is implemented by decoding the various elements in the same manner as the client or server in the conversation would. When the elements of the protocol are identified, the IDS applies rules defined by the request for comments (RFCs) to look for violations. In some instances, these violations are found with pattern matches within a specific protocol field, and some require more advanced techniques that account for such variables as the length of a field or the number of arguments.

Consider the fictitious example of the *gwb* attack for illustration purposes. Suppose that the base protocol that the attack is being run over is the fictitious OBL protocol, and more specifically, assume that the attack requires that the illegal fictitious argument *gpp* must be passed in the OBL Type field. To further complicate the situation, assume that the Type field is preceded by a field of variable length called OBL Options. The valid list of fictitious options are *gppi, nppi, upsnfs*, and *cvjmep*. Using the simple or the stateful pattern-matching algorithm in this case leads to false positives because the option *gppi* contains the pattern that is being searched for. In addition, because the field lengths are variable, it would be impossible to limit such false positives by specifying search start and stop locations. The only way to be certain that *gpp* is being passed in as the OBL type argument is to fully decode the protocol.

If the protocol allows for behavior that the pattern-matching algorithms have difficulty dealing with, not doing full protocol decodes can also lead to false negatives. For example, if the OBL protocol allows every other byte to be a NULL if a value is set in the OBL header, the pattern matchers would fail to see fx00ox00ox00. The protocol decode-enabled analysis engine would strip the NULLS and fire the alarm as expected, assuming that *gpp* was in the Type field. Thus, with the preceding in mind, the advantages of the protocol decode-based analysis are as follows:

- This method can allow for direct correlation of an exploit.
- This method can be more broad and general to allow catching variations on a theme.
- This method minimizes the chance for false positives if the protocol is well defined and enforced.
- This method reliably alerts on the violation of the protocol rules as defined in the rules script.

The disadvantages of this technique are as follows:

- This method can lead to high false-positive rates if the RFC is ambiguous and allows developers the discretion to interpret and implement as they see fit. These gray area protocol violations are very common.
- This method requires longer development times to properly implement the protocol parser.

Heuristic-based Analysis

A good example of this type of signature is a signature that would be used to detect a port sweep. This signature looks for the presence of a threshold number of unique ports being touched on a particular machine. The signature may further restrict itself through the specification of the types of packets that it is interested in (that is, SYN packets). Additionally, there may be a requirement that all the probes must originate from a single source. Signatures of this type require some threshold manipulations to make them conform to the utilization patterns on the network they are monitoring. This type of signature may be used to look for very complex relationships as well as the simple statistical example given.

The advantages for heuristic-based signature analysis are that some types of suspicious and/or malicious activity cannot be detected through any other means. The

disadvantages are that algorithms may require tuning or modification to better conform to network traffic and limit false positives.

Anomaly-based Analysis

From what is seen normally, anomaly-based signatures are typically geared to look for network traffic that deviates. The biggest problem with this methodology is to first define what normal is. Some systems have hardcoded definitions of normal, and in this case they could be considered heuristic-based systems. Some systems are built to learn normal, but the challenge with these systems is in eliminating the possibility of improperly classifying abnormal behavior as normal. Also, if the traffic pattern being learned is assumed to be normal, the system must contend with how to differentiate between allowable deviations and those not allowed or representing attack-based traffic. The work in this area has been mostly limited to academia, although there are a few commercial products that claim to use anomaly-based detection methods. A subcategory of this type of detection is the profile-based detection methods. These systems base their alerts on changes in the way that users or systems interact on the network. They incur many of the same limitations and problems that the overarching category has in inferring the intent of the change in behavior.

Statistical anomalies may also be identified on the network either through learning or teaching of the statistical norms for certain types of traffic, for example, systems that detect traffic floods, such as UDP, TCP, or ICMP floods. These algorithms compare the current rate of arrival of traffic with a historical reference; based on this, the algorithms will alert to statistically significant deviations from the historical mean. Often, a user can provide the statistical threshold for the alerts. The advantages for anomaly-based detection are as follows:

- If this method is implemented properly, it can detect unknown attacks.
- This method offers low overhead because new signatures do not have to be developed.
- In general, these systems are not able to give you intrusion data with any granularity. It looks like something terrible may have happened, but the systems cannot say definitively.
- This method is highly dependent on the environment in which the systems learn what normal is.

The following are Freeware tools to monitor and analyze network activities:

- Network Scanner, Nmap, is available from www.insecure.org. Nmap is a free open-source utility to monitor open ports on a network. The MS-Windows version is a zip file by the name nmap-3.75-win32. zip. You also need to download a packet capture library, WinPcap, under Windows. It is available from http://winpcap.polito.it. In addition to these programs, you need a utility to unzip the zipped file, which you can download from various Internet sites.
- PortPeeker is a freeware utility for capturing network traffic for TCP, UDP, or ICMP protocols. With PortPeeker you can easily and quickly see what traffic is being sent to a given port. This utility is available from www.Linklogger.com.
- Port-scanning tools such as Fport 2.0 or higher and SuperScan 4.0 or higher are easy to use and freely available from www.Foundstone.com.
- Network sniffer Ethereal is available from www.ethereal.com. Ethereal is a packet sniffer and analyzer for a variety of protocols.
- EtherSnoop light is a free network sniffer designed for capturing and analyzing the packets going through the network. It captures the data passing through your network Ethernet card, analyzes the data, and represents it in a readable form. EtherSnoop light is a fully configurable network analyzer program for Win32 environments. It is available from www.arechisoft.com.
- A fairly advanced tool, Snort, an open-source NIDS, is available from www.snort.org.
- UDPFlood is a stress testing tool that could be identified as a DoS agent; it is available from www.Foundstone.com.
- An application that allows you to generate a SYN attack with a spoofed address so that the remote host's CPU cycle's get tied up is Attacker, and is available from www.komodia.com.

Finally, organizations employing legacy LANs should be aware of the limited and weak security controls available to protect communications. Legacy LANs are particularly susceptible to loss of confidentiality, integrity, and availability. Unauthorized users have access to well-documented security flaws and exploits that can easily compromise an organization's systems and information, corrupt the organization's data, consume network bandwidth, degrade network performance, launch attacks that prevent authorized users from accessing the network, or use the organization's resources to launch attacks on other networks. Organizations should mitigate risks to their LANs by applying countermeasures to address specific threats and vulnerabilities. So, with the preceding in mind, let's briefly look at a local area network security countermeasures checklist, which describes management, operational, and technical countermeasures that can be effective in reducing the risks commonly associated with legacy LANs.

An Agenda for Action for Local Area Network Security Countermeasures Implementation Activities

Policy considerations for legacy LANs should include the following (check all tasks completed):

Roles and Responsibilities:

_____**1.** Which users or groups of users are and are not authorized to use organization LANs?

_____**2.** Which parties are authorized and responsible for installing and configuring access points (APs) and other LAN equipment?

LAN Infrastructure Security:

_____**3.** Physical security requirements for LANs and LAN devices, including limitations on the service areas of LANs.

_____**4.** Types of information that may and may not be sent over LANs, including acceptable use guidelines.

_____**5.** How LAN transmissions should be protected, including requirements for the use of encryption and for cryptographic key management.

LAN Client Device Security:

_____**6.** The conditions under which LAN client devices are and are not allowed to be used and operated.

_____**7.** Standard hardware and software configurations that must be implemented on LAN client devices to ensure the appropriate level of security.

_____**8.** Limitations on how and when LAN clients device may be used, such as specific locations.

_____**9.** Guidelines on reporting losses of LAN client devices and reporting LAN security incidents.

_____**10.** Guidelines for the protection of LAN client devices to reduce theft.

LAN Security Assessments:

_____**11.** The frequency and scope of LAN security assessments.

_____**12.** The actions to be taken to address rogue or misconfigured devices that are identified.

Other Recommendations for Management Countermeasures are as Follows:

_____**13.** Consider designating an individual to track the progress of security standards, features, threats, and vulnerabilities. This helps to ensure the continued secure implementation of LAN technology.

_____**14.** Maintain an inventory of legacy access points (APs) and connecting devices. This inventory is useful when conducting audits of technologies, particularly in identifying rogue devices.

25. LOCAL AREA NETWORK SECURITY COUNTERMEASURES IMPLEMENTATION CHECKLIST

With this checklist, these countermeasures do not guarantee a secure LAN environment and cannot prevent all adversary penetrations. Also, security comes at a cost—financial expenses related to security equipment, inconvenience, maintenance, and operation. Each organization needs to evaluate the acceptable level of risk based on numerous factors, which will affect the level of security implemented by that organization. To be effective, LAN security should be incorporated throughout the entire life cycle of LAN solutions. Organizations should create a networking security policy that addresses legacy LAN security. Such a policy and an organization's ability to enforce compliance with it are the foundations for all other countermeasures (see checklist: "An Agenda For Action For Local Area Network Security Countermeasures Implementation Activities"):

26. SUMMARY

Local area networks (LANs) are significantly impacting the way organizations do business. As more and more critical work migrates from mainframes to LANs, the need for better controls becomes apparent. This chapter discussed the security and control issues involved with LANs; the types of critical and sensitive data now residing on LANs; the impact of loss, change or disclosure; and, realistic remedies for identified vulnerabilities. Also covered, were how transition technologies, topologies, and architectures create complex security, recovery, and integrity problems. In addition, the security features of popular LAN systems software and add-on packages were also identified. Next, the need for policies, procedures, and administrative controls were covered.

In conclusion, this chapter discussed the basics of how and where to implement effective controls in a local area network (LAN). Security pitfalls existing in both the hardware and software components that make up a LAN were identified. The significant challenges presented by the fast growth of LANs in the workplace was met head on with guidelines for reducing security exposures. Although this chapter di not address the specific implementations of any single network operating system, the topics discussed apply to all of these systems.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Most LANs are designed as collapsed backbone networks using a layer-1 or layer-4 switch.
2. True or False? The LAN consists of a number of segments reflecting the network structure.
3. True or False? The most trusted users belong to the Internet.
4. True or False? During the final design phase of a network, the network architects assess the types of risks to the network; as well as, the costs of recovering from attacks for all the resources that have been compromised.
5. True or False? The fundamental goals of security policy are to allow uninterrupted access to the network resources for authenticated users and to deny access to unauthenticated users.

Multiple Choice

1. The critical functions of a good security policy include the following, except which one?
   - **A.** Appoint a security administrator who is conversant with users' demands and on a continual basis is prepared to accommodate the user community's needs.
   - **B.** Monitor and analyze user and system activities.
   - **C.** Set up a hierarchical security policy to reflect the corporate structure.
   - **D.** Define ethical Internet access capabilities.
   - **E.** Provide a set of incident-handling procedures.
2. IDSs perform the following functions, except which one?
   - **A.** Monitor and analyze user and system activities.
   - **B.** Verify the integrity of data files.
   - **C.** Customize the availability of 'apps' (applications).
   - **D.** Audit system configuration files.
   - **E.** Recognize activity of patterns, reflecting known attacks.
3. IDSs perform the following critical functions, except which one?
   - **A.** Can impose a greater degree of flexibility to the security infrastructure of the network.
   - **B.** Monitors the functionality of routers, including firewalls, key servers, and critical switches.
   - **C.** Can help resolve audit trails, thus often exposing problems before they lead to loss of data.
   - **D.** Can trace the mobile hardware industry.
   - **E.** Can make possible security management of a network by nonexpert staff.
4. Some of the common malicious attacks on networks include the following, except which one?
   - **A.** IP address spoofing
   - **B.** MAC address spoofing
   - **C.** ARP cache poisoning
   - **D.** DNS name corruption
   - **E.** PPTP VPNs address hacking
5. The following points should be noted about network intrusion detection system (NIDS), except which one?
   - **A.** Inbound and outbound NIDS malware scanning.
   - **B.** One NIDS is installed per LAN (Ethernet) segment.
   - **C.** Place NIDS on the auxiliary port on the switch and then link all the ports on the switch to that auxiliary port.
   - **D.** When the network is saturated with traffic, the NIDS might drop packets and thus create a potential "hole."
   - **E.** If the data packets are encrypted, the usefulness of an IDS is questionable.

EXERCISE

Problem

What minimum requirements does a computer need to meet to be able to connect to a local area network?

Hands-On Projects

Project

A medium size company needs to know what components they will need to establish a Local Area Network. They plan to have 1,200 users with e-mail, file and print, and Internet services. They also plan to have 20 servers used as LAN, proxy, and database servers. Four departments will need sufficient bandwidth and access applications from a database server. They are also going to expand to eight branch offices located in different states, two with only 10 users needing just a single Internet. What hardware components does the company need to build the LAN for all areas?

Case Projects

Problem

How can an organization correctly route traffic? A small organization has an application server with two network interface cards (NICs): LAN (A) equals a corporate network (in which clients connect to a server for application use); and, LAN (B) equals a digital subscriber line (DSL) Internet and remote connection. The application on this

application server is designed to send alerts to the clients (connected via LAN (A)) and it also has email functionality (configured using POP3) that needs to be outbound via LAN (B), due to LAN (A) blocking this traffic. Right now, LAN (A) does not have a default gateway defined, which is allowing the email functionality to work just fine; clients can connect to the servers application via LAN (A) as well; but, the alerts that the application is supposed to send to the client does not work. When LAN (B) is disabled completely, the clients connect to the server application; and, the application successfully sends alerts to the clients as it is designed to do; but, the email functionality no longer works because of the blocked outbound traffic. So, what is the proper way to set this up? Is it something that can be corrected by using static routes? Routing and Remote Access Service (RRAS) perhaps?

Optional Team Case Project

Problem

How would a small company go about connecting a LAN to WAN server? In other words, how would the company connect their default LAN IP (193.279.2. . . .) through a Cisco router to a WAN IP (213.81. . . .)?

With the rapid development of technology in wireless communication and microchips, wireless technology has been widely used in various application areas. The proliferation of wireless devices and wireless networks in the past decade shows the widespread use of wireless technology.

Wireless networks are a general term to refer to various types of networks that communicate without the need of wire lines. Wireless networks can be broadly categorized into two classes based on the structures of the networks: wireless ad hoc networks and cellular networks. The main difference between these two is whether a fixed infrastructure is present.

Three of the well-known cellular networks are the GSM network, the CDMA network, and the 802.11 wireless LAN. The GSM network and the CDMA network are the main network technologies that support modern mobile communication, with most of the mobile phones and mobile networks that are built based on these two wireless networking technologies and their variants. As cellular networks require fixed infrastructures to support the communication between mobile nodes, deployment of the fixed infrastructures is essential. Further, cellular networks require serious and careful topology design of the fixed infrastructures before deployment, because the network topologies of the fixed infrastructures are mostly static and will have a great impact on network performance and network coverage.

Wireless ad hoc networks do not require a fixed infrastructure; thus it is relatively easy to set up and deploy a wireless ad hoc network (see Figure 15.1). Without the fixed infrastructure, the topology of a wireless ad hoc network is dynamic and changes frequently. It is not realistic to assume a static or a specific topology for a wireless ad hoc network. On the other hand, wireless ad hoc networks need to be self-organizing; thus mobile nodes in a wireless ad hoc network can adapt to the change of topology and establish cooperation with other nodes at runtime.

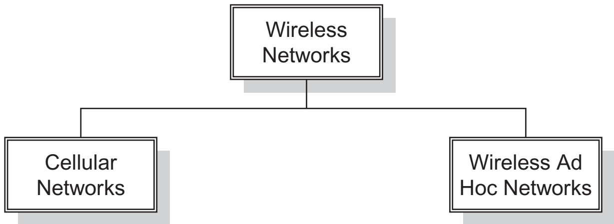

FIGURE 15.1 Classification of wireless networks.

Besides the conventional wireless ad hoc networks, there are two special types that should be mentioned: wireless sensor networks and wireless mesh networks. Wireless sensor networks are wireless ad hoc networks, most of the network nodes of which are sensors that monitor a target scene. The wireless sensors are mostly deprived devices in terms of computation power, power supply, bandwidth, and other computation resources. Wireless mesh networks are wireless networks with either a full mesh topology or a partial mesh topology in which some or all nodes are directly connected to all other nodes. The redundancy in

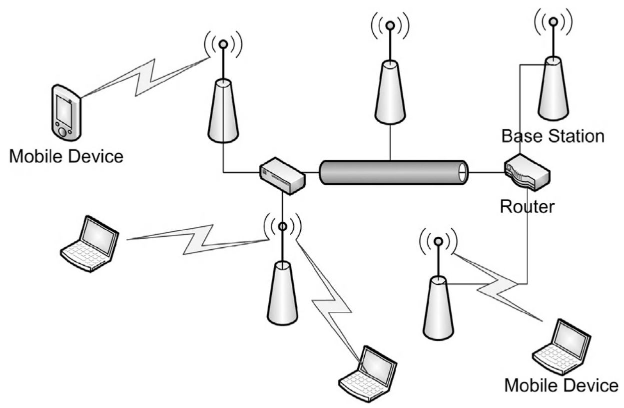

FIGURE 15.2 Cellular networking.

connectivity of wireless networks provides great reliability and excellent flexibility in network packet delivery.

1. CELLULAR NETWORKS

Cellular networks require fixed infrastructures to work (see Figure 15.2). A cellular network comprises a fixed infrastructure and a number of mobile nodes. Mobile nodes connect to the fixed infrastructure through wireless links. They may move around from within the range of one base station to outside the range of the base station, and they can move into the ranges of other base stations. The fixed infrastructure is stationary, or mostly stationary, including base stations, links between base stations, and possibly other conventional network devices such as routers. The links between base stations can be either wired or wireless. The links should be more substantial than those links between base stations and mobile nodes in terms of reliability, transmission range, bandwidth, and so on.

The fixed infrastructure serves as the backbone of a cellular network, providing high speed and stable connection for the whole network, compared to the connectivity between a base station and a mobile node. In most cases, mobile nodes do not communicate with each other directly without going through a base station. A packet from a source mobile node to a destination mobile node is likely to be first transmitted to the base station to which the source mobile node is connected. The packet is then relayed within the fixed infrastructures until reaching the destination base station to which the destination mobile node is connected. The destination base station can then deliver the packet to the destination mobile node to complete the packet delivery.

Cellular Telephone Networks

Cellular telephone networks offer mobile communication for most of us. With a cellular telephone network, base stations are distributed over a region, with each base station covering a small area. Each part of the small area is called a *cell*. Cell phones within a cell connect to the base station of the cell for communication. When a cell phone moves from one cell to another, its connection will also be migrated from one base station to a new base station. The new base station is the base station of the cell into which the cell phone just moved.

Two of the technologies are the mainstream for cellular telephone networks: the global system for mobile communication (GSM) and code division multiple access (CDMA).

GSM is a wireless cellular network technology for mobile communication that has been widely deployed in most parts of the world. Each GSM mobile phone uses a pair of frequency channels, with one channel for sending data and another for receiving data. Time division multiplexing (TDM) is used to share frequency pairs by multiple mobiles.

CDMA is a technology developed by a company named Qualcomm and has been accepted as an international standard. CDMA assumes that multiple signals add linearly, instead of assuming that colliding frames are completely garbled and of no value. With coding theory and the new assumption, CDMA allows each mobile to transmit over the entire frequency spectrum at all times. The core algorithm of CDMA is how to extract data of interest from the mixed data.

802.11 Wireless LANs

Wireless LANs are specified by the IEEE 802.11 series standard [1], which describes various technologies and protocols for wireless LANs to achieve different targets, allowing the maximum bit rate from 2 Mbits per second to 248 Mbits per second. Wireless LANs can work in either access point (AP) mode or ad hoc mode, as shown in Figure 15.3. When a wireless LAN is working in AP mode, all communication passes through a base station, called an *access point*. The access point then passes the communication data to the destination node, if it is connected to the access point, or forwards the communication data to a router for further routing and relaying. When working in ad hoc mode, wireless LANs work in the absence of base stations. Nodes directly communicate with other nodes within their transmission range, without depending on a base station.

One of the complications that 802.11 wireless LANs incur is medium access control in the data link layer. Medium access control in 802.11 wireless LANs can be either distributed or centralized control by a base station. The distributed medium access control relies on the Carrier Sense Multiple Access (CSMA) with Collision Avoidance (CSMA/CA) protocol. CSMA/CA allows network nodes to compete to transmit data when a channel is idle and uses the Ethernet binary exponential backoff algorithm to decide a waiting time before retransmission when a

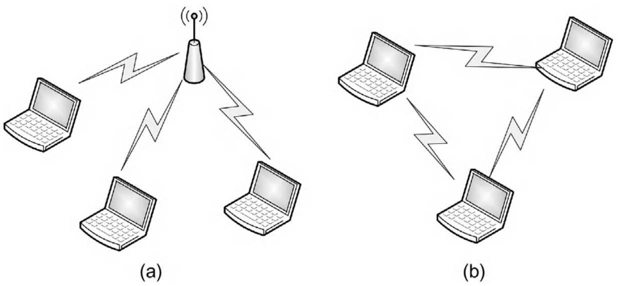

FIGURE 15.3 (a) A wireless network in AP mode; (b) a wireless network in ad hoc mode.

collision occurs. CSMA/CA can also operate based on MACAW (Multiple Access with Collision Avoidance for Wireless) using virtual channel sensing. Request packets and clear-to-send (CTS) packets, are broadcast before data transmission by the sender and the receiver, respectively. All stations within the range of the sender or the receiver will keep silent in the course of data transmission to avoid interference on the transmission.

The centralized medium access control is implemented by having the base station broadcast a beacon frame periodically and poll nodes to check whether they have data to send. The base station serves as a central control over the allocation of the bandwidth. It allocates bandwidth according to the polling results. All nodes connected to the base station must behave in accordance with the allocation decision made by the base station. With the centralized medium access control, it is possible to provide quality-of-service guarantees because the base station can control on the allocation of bandwidth to a specific node to meet the quality requirements.

2. WIRELESS AD HOC NETWORKS

Wireless ad hoc networks are distributed networks that work without fixed infrastructures and in which each network node is willing to forward network packets for other network nodes. The main characteristics of wireless ad hoc networks are as follows:

- Wireless ad hoc networks are distributed networks that do not require fixed infrastructures to work. Network nodes in a wireless ad hoc network can be randomly deployed to form the wireless ad hoc network.
- Network nodes will forward network packets for other network nodes. Network nodes in a wireless ad hoc network directly communicate with other nodes within their ranges. When these networks communicate with network nodes outside of their ranges, network packets will be forwarded by the nearby network nodes; and, other nodes that are on the path from the source nodes to the destination nodes.
- Wireless ad hoc networks are self-organizing. Without fixed infrastructures and central administration, wireless ad hoc networks must be capable of establishing cooperation between nodes on their own. Network nodes must also be able to adapt to changes in the network, such as the network topology.
- Wireless ad hoc networks have dynamic network topologies. Network nodes of a wireless ad hoc network connect to other network nodes through wireless links. The network nodes are mostly mobile. The topology of a wireless ad hoc network can change from time to time, since network nodes move around from within the range to the outside, and new network nodes may join the network, just as existing network nodes may leave the network.

Wireless Sensor Networks

A wireless sensor network is an ad hoc network mainly comprising sensor nodes, which are normally used to monitor and observe a phenomenon or a scene. The sensor nodes are physically deployed within or close to the phenomenon or the scene. The collected data will be sent back to a base station from time to time through routes dynamically discovered and formed by sensor nodes.

Sensors in wireless sensor networks are normally small network nodes with very limited computation power, limited communication capacity, and limited power supply. Thus a sensor may perform only simple computation and can communicate with sensors and other nodes within a short range. The life spans of sensors are also limited by the power supply.

Wireless sensor networks can be self-organizing, since sensors can be randomly deployed in some inaccessible areas. The randomly deployed sensors can cooperate with other sensors within their range to implement the task of monitoring or observing the target scene or the target phenomenon and to communicate with the base station that collects data from all sensor nodes. The cooperation might involve finding a route to transmit data to a specific destination, relaying data from one neighbor to another neighbor when the two neighbors are not within reach of each other, and so on.

Wireless Multimedia Sensor Networks

Wireless multimedia sensor networks (WMSNs), developed based on wireless sensor networks, are the networks of wireless, interconnected smart devices that enable processing video and audio streams, still images, and scalar sensor data. WMSNs will enable the retrieval of multimedia streams and will store, process in real-time, correlate, and fuse multimedia content captured by heterogeneous sources. The characteristics of a WMSN diverge consistently from traditional network paradigms, such as the Internet and even from scalar sensor networks. Most potential applications of a WMSN require the sensor network paradigm to

be rethought to provide mechanisms to deliver multimedia content with a predetermined level of quality of service (QoS). Whereas minimizing energy consumption has been the main objective in sensor network research, mechanisms to efficiently deliver application-level QoS and to map these requirements to network-layer metrics, such as latency and jitter, have not been primary concerns. Delivery of multimedia content in sensor networks presents new, specific system design challenges, which are the object of this article. potential to enable many new applications, includeing Multimedia Surveillance Sensor Networks, Traffic Avoidance, Enforcement, and Control SystemsAdvanced Health Care Delivery. Environmental and Structural Monitoring and Industrial Process Control.

Internet of Things

The Internet of Things (IoT) is an emerging global Internetbased information architecture facilitating the exchange of goods and services in global supply chain networks, the connection of physical things to the Internet makes it possible to access remote sensor data and to control the physical world from a distance. The applications of Internet of Things are based on real physical objectives. For example, the lack of certain goods would automatically be reported to the provider which in turn immediately causes electronic or physical delivery. From a technical point of view, the IoT architecture is based on data communication tools, primarily RFID-tagged items (Radio-Frequency Identification). The IoT has the purpose of providing an IT-infrastructure facilitating the exchanges of ''things'' in a secure and reliable manner. The most popular industry proposal for the new IT-infrastructure of the IoT is based on an Electronic Product Code (EPC), introduced by EPCglobal and GS1. The ''things'' are physical objects carrying RFID tags with a unique EPC; the infrastructure can offer and query EPC Information Services (EPCIS) both locally and remotely to clients. Since some important business processes are concerned, a high degree of reliability about IoT is needed. Generally, the following security and privacy requirements are necessary for IoT:

1. Resilience to attacks: IoT system has to avoid single points of failure and should adjust itself to node failures.
2. Data authentication: Retrieved address and object information must be authenticated is a principle for efficient applications.
3. Access control: Information providers of IoT must be able to implement access control scheme on their confidential data.
4. Client privacy: there should be suitable measures to prevent others retrieving clients' private information and data.

Mesh Networks

One of the emerging technologies of wireless network are wireless mesh networks (WMNs). Nodes in a WMN include mesh routers and mesh clients. Each node in a WMN works as a router as well as a host. When it's a router, each node needs to perform routing and to forward packets for other nodes when necessary, such as when two nodes are not within direct reach of each other and when a route to a specific destination for packet delivery is required to be discovered.

Mesh routers may be equipped with multiple wireless interfaces, built on either the same or different wireless technologies, and are capable of bridging different networks. Mesh routers can also be classified as access mesh routers, backbone mesh routers, or gateway mesh routers. Access mesh routers provide mesh clients with access to mesh networks; backbone mesh routers form the backbone of a mesh network; and a gateway mesh router connects the backbone to an external network.

Each mesh client normally has only one network interface that provides network connectivity with other nodes. Mesh clients are not usually capable of bridging different networks, which is different from mesh routers.

Similar to other ad hoc networks, a wireless mesh network can be self-organizing. Thus nodes can establish and maintain connectivity with other nodes automatically, without human intervention. Wireless mesh networks can divided into backbone mesh networks and access mesh networks.

3. SECURITY PROTOCOLS

Wired Equivalent Privacy (WEP) was defined by the IEEE 802.11 standard [1]. WEP is designed to protect linkage-level data for wireless transmission by providing confidentiality, access control, and data integrity, to provide secure communication between a mobile device and an access point in a 802.11 wireless LAN.

4. WEP

Implemented based on shared key secrets and the RC4 stream cipher [2], WEP's encryption of a frame includes two operations (see Figure 15.4). It first produces a checksum of the data, and then it encrypts the plaintext and the checksum using RC4:

- *Checksumming*. Let c be an integrity checksum function. For a given message M, a checksum $c(M)$ is

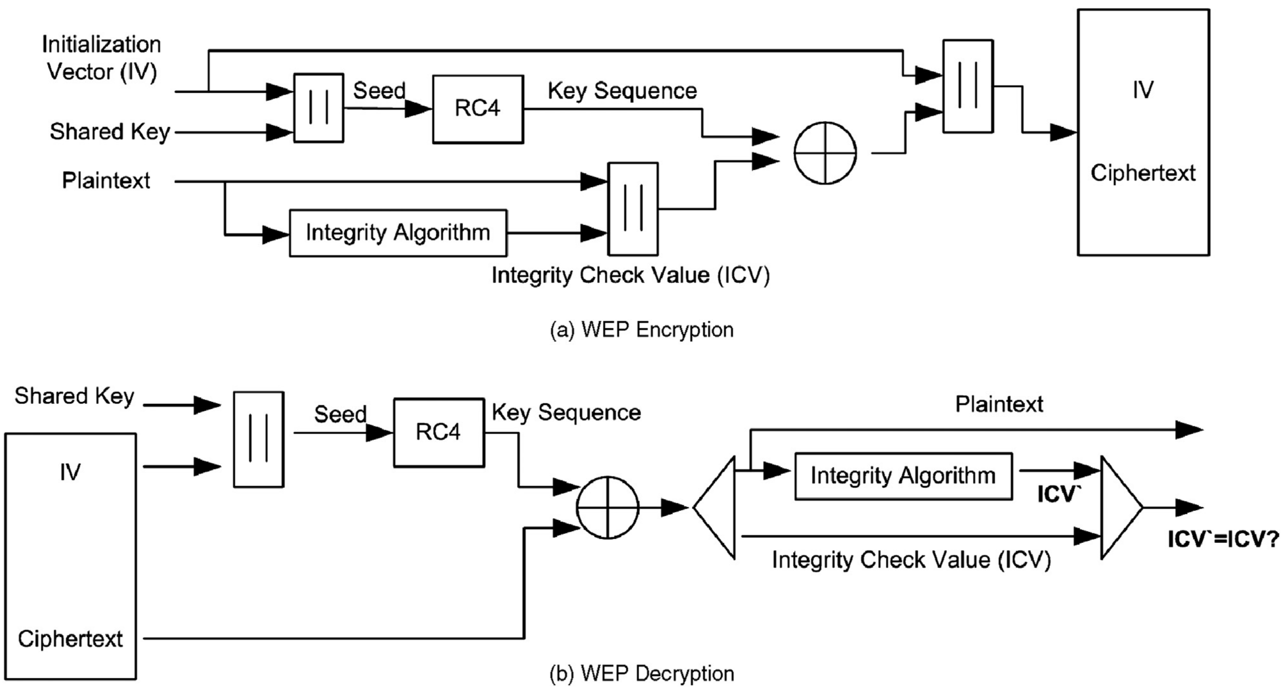

FIGURE 15.4 WEP encryption and decryption.

calculated and then concatenated to the end of M, obtaining a plaintext $P = <M, c(M)>$. Note that the checksum $c(M)$ does not depend on the shared key.

- *Encryption.* The shared key k is concatenated to the end of the initialization vector (IV) v, forming $<v,k>$. $<v,k>$ is then used as the input to the RC4 algorithm to generate a keystream $RC4(v,k)$. The plaintext P is exclusive-or' ed (XOR, denoted by $\oplus$) with the keystream to obtain the ciphertext: $C = P \oplus RC4(v,k)$.

Using the shared key k and the IV v, WEP can greatly simplify the complexity of key distribution because it needs only to distribute k and v but can achieve a relatively very long key sequence. IV changes from time to time, which will force the *RC 4* algorithm to produce a new key sequence, avoiding the situation where the same key sequence is used to encrypt a large amount of data, which potentially leads to several types of attacks [3,4].

WEP combines the shared key k and the IV v as inputs to seed the *RC 4* function. 802.11B [1] specifies that the seed shall be 64 bits long, with 24 bits from the IV v and 40 bits from the shared key k. Bits 0 through 23 of the seed contain bits 0 through 23 of the IV v, and bits 24 through 63 of the seed contain bits 0 through 39 of the shared key k. When a receiver receives the ciphertext C, it will XOR the ciphertext C with the corresponding keystream to produce the plaintext M' as follows:

$$M' = C \oplus RC4(k,v) = (P \oplus RC4(k,v)) \oplus RC4(k,v) = M$$

WPA and WPA2

Wi-Fi Protected Access (WPA) is specified by the IEEE 802.11i standard. The standard is aimed at providing a stronger security compared to WEP and is expected to tackle most of the weakness found in WEP [5–7].

WPA

WPA has been designed to target both enterprise and consumers. Enterprise deployment of WPA is required to be used with IEEE 802.1x authentication, which is responsible for distributing different keys to each user. Personal deployment of WPA adopts a simpler mechanism, which allows all stations to use the same key. This mechanism is called the *Pre-Shared Key* (PSK) mode.

The WPA protocol works in a similar way to WEP. WPA mandates the use of the *RC 4* stream cipher with a 128 – bit key and a 48 – bit initialization vector (IV), compared with the 40 – bit key and the 24 – bit IV in WEP.

WPA also has a few other improvements over WEP, including the Temporal Key Integrity Protocol (TKIP) and the Message Integrity Code (MIC). With TKIP, WPA will dynamically change keys used by the system periodically. With the much larger IV and the dynamically changing key, the stream cipher *RC*4 is able to produce a much longer keystream. The longer keystream improved WPA's protection against the well-known key recovery attacks on WEP, since finding two packets encrypted

using the same key sequences is literally impossible due to the extremely long keystream.

With MIC, WPA uses an algorithm named Michael to produce an authentication code for each message, which is termed the *message integrity code*. The message integrity code also contains a frame counter to provide protection over replay attacks.

WPA uses the Extensible Authentication Protocol (EAP) framework [8] to conduct authentication. When a user (supplicant) tries to connect to a network, an authenticator will send a request to the user asking the user to authenticate herself using a specific type of authentication mechanism. The user will respond with corresponding authentication information. The authenticator relies on an authentication server to make the decision regarding the user's authentication.

WPA2

WPA2 is not much different from WPA. Though TKIP is required in WPA, Advanced Encryption Standard (AES) is optional. This is aimed to provide backward compatibility for WPA over hardware designed for WEP, as TKIP can be implemented on the same hardware as those for WEP, but AES cannot be implemented on this hardware. TKIP and AES are both mandatory in WPA2 to provide a higher level of protection over wireless connections. AES is a block cipher, which can only be applied to a fixed length of data block. AES accepts key sizes of 128 bits, 196 bits, and 256 bits.

Besides the mandatory requirement of supporting AES, WPA2 also introduces supports for fast roaming of wireless clients migrating between wireless access points. First, WPA2 allows the caching of a Pair-wise Master Key (PMK), which is the key used for a session between an access point and a wireless client; thus a wireless client can reconnect a recently connected access point without having to reauthenticate. Second, WPA2 enables a wireless client to authenticate itself to a wireless access point that it is moving to while the wireless client maintains its connection to the existing access point. This reduces the time needed for roaming clients to move from one access point to another, and it is especially useful for timing-sensitive applications.

SPINS: Security Protocols for Sensor Networks

Sensor nodes in sensor networks are normally low-end devices with very limited resources, such as memory, computation power, battery, and network bandwidth.

Perrig et al. [9] proposed a family of security protocols named SPINS, which were specially designed for low-end devices with severely limited resources, such as sensor nodes in sensor networks. SPINS consists of two building blocks: Secure Network Encryption Protocol (SNEP) and the "micro" version of the Timed, Efficient, Streaming, Loss-tolerant Authentication Protocol (μTESLA). SNEP uses symmetry encryption to provide data confidentiality, two-party data authentication, and data freshness. μTESLA provides authentication over broadcast streams. SPINS assumes that each sensor node shares a master key with the base station. The master key serves as the base of trust and is used to derive all other keys.

SNEP

As illustrated in Figure 15.5, SNEP uses a block cipher to provide data confidentiality and message authentication code (MAC) to provide authentication. SNEP assumes a shared counter C between the sender and the receiver and two keys, the encryption key K_{encr} and the authentication key K_{mac}. For an outgoing message D, SNEP processes it as follows:

- The message D is first encrypted using a block cipher in counter mode with the key K_{encr} and the counter C, forming the encrypted text $E = \{D\} < Kencr, C >$.
- A message authentication code is produced for the encrypted text E with the key K_{mac} and the counter C, forming the MAC $M = MAC(K_{mac}, C|E)$ where $MAC()$ is a one-way function and $C|E$ stands for the concatenation of C and E.
- SNEP increments the counter C.

To send the message D to the recipient, SNEP actually sends out E and M. In other words, SNEP encrypts D to E using the shared key K_{encr} between the sender and the receiver to prevent unauthorized disclosure of the data, and it uses the shared key K_{mac}, known only to the sender and the receiver, to provide message authentication. Thus data confidentiality and message authentication can both be implemented.

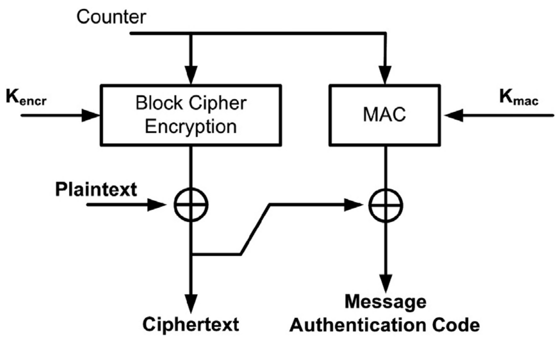

FIGURE 15.5 Sensor Network Encryption Protocol (SNEP).

The message D is encrypted with the counter C, which will be different in each message. The same message D will be encrypted differently even it is sent multiple times. Thus semantic security is implemented in SNEP. The MAC is also produced using the counter C; thus it enables SNEP to prevent replying to old messages.

μTESLA

TESLA [10−12] was proposed to provide message authentication for multicast. TESLA does not use any asymmetry cryptography, which makes it lightweight in terms of computation and overhead of bandwidth.

μTESLA is a modified version of TESLA, aiming to provide message authentication for multicasting in sensor networks. The general idea of μTESLA is that the sender splits the sending time into intervals. Packets sent out in different intervals are authenticated with different keys. Keys to authenticate packets will be disclosed after a short delay, when the keys are no longer used to send out messages. Thus packets can be authenticated when the authentication keys have been disclosed. Packets will not be tampered with while they are in transit since the keys have not been disclosed yet. The disclosed authentication keys can be verified using previous known keys to prevent malicious nodes from forging authentication keys.

μTESLA has four phases: sender setup, sending authenticated packets, bootstrapping new receivers, and authenticating packets. In the sender setup phase, a sender generates a chain of keys, K_i $(0 \leq i \leq n)$. The keychain is a one-way chain such that K_i can be derived from K_j if $i \leq j$, such as a keychain K_i (i = 0,. . .,n), $K_i = F(K_{i+1})$, where F is a one-way function. The sender also decides on the starting time T_0, the interval duration T_{int}, and the disclosure delay d (unit is interval), as shown in Figure 15.6.

To send out authenticated packets, the sender attaches a MAC with each packet, where the MAC is produced using a key from the keychain and the data in the network packet. μTESLA has specific requirements on the use of keys for producing MACs. Keys are used in the same order as the key sequence of the keychain. Each of the keys is used in one interval only. For the interval $T_i = \tau_0 + i \times T_{int}$, the key K_i is used to produce the MACs for the messages sent out in the interval T_i Keys are disclosed with a fixed delay d such that the key K_i used in interval T_i will be disclosed in the interval T_{i+d} The sequence of key usage and the sequence of key disclosure are demonstrated in Figure 15.6.

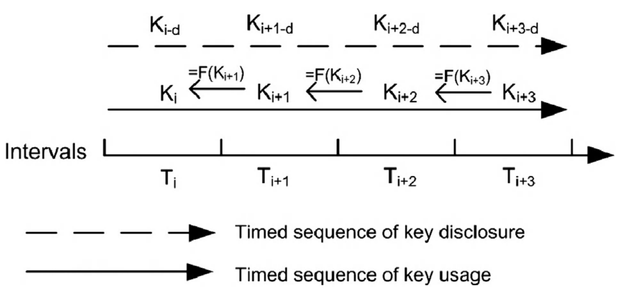

FIGURE 15.6 Sequences of intervals, key usages, and key disclosure.

To bootstrap a new receiver, the sender needs to synchronize the time with the receiver and needs to inform the new receiver of a key K_j that is used in a past interval T_j, the interval duration T_{int}, and the disclosure delay d. With a previous key K_j, the receiver will be able to verify any key K_p where $j \leq p$ using the one-way keychain's property. After this, the new receiver will be able to receive and verify data in the same way as other receivers that join the communication prior to the new receiver.

To receive and authenticate messages, a receiver will check all incoming messages if they have been delayed for more than d. Messages with a delay greater than d will be discarded, since they are suspect as fake messages constructed after the key has been disclosed. The receiver will buffer the remaining messages for at least d intervals until the corresponding keys are disclosed. When a key K_i is disclosed at the moment $T_i + d$, the receiver will verify K_i using K_{i-1} by checking if $K_{i-1} = F(K_i)$. Once the key K_i is verified, K_i will be used to authenticate those messages sent in the interval T_i.

5. SECURE ROUTING

Secure Efficient Ad hoc Distance (SEAD) [13] vector routing is adesign based on Destination-Sequenced Distance Vector (DSDV) routing [14]. SEAD augments DSDV with authentication to provide security in the construction and exchange of routing information.

SEAD

Distance vector routing works as follows. Each router maintains a routing table. Each entry of the table contains a specific destination, a metric (the shortest distance to the destination), and the next hop on the shortest path from the current router to the destination. For a packet that needs to be sent to a certain destination, the router will look up the destination from the routing table to get the matching entry. Then the packet is sent to the next hop specified in the entry.

To allow routers to automatically discover new routes and maintain their routing tables, routers exchange routing information periodically. Each router advises its neighbors of its own routing information by broadcasting its routing table to all its neighbors. Each router will update its routing table according to the information it hears from its neighbors. If a new destination is found

from the information advertised by a neighbor, a new entry is added to the routing table with the metric recalculated based on the advertised metric and the linking between the router and the neighbor. If an existing destination is found, the corresponding entry is updated only when a new path that is shorter than the original one has been found. In this case, the metric and the next hop for the specified destination are modified based on the advertised information.

Though distance vector routing is simple and effective, it suffers from possible routing loops, also known as the counting to infinity problem. DSDV [14] is one of the extensions to distance vector routing to tackle this issue. DSDV augments each routing update with a sequence number, which can be used to identify the sequence of routing updates, preventing routing updates being applied in an out-of-order manner. Newer routing updates are advised with sequence numbers greater than those of the previous routing updates. In each routing update, the sequence number will be incremented to the next even number. Only when a broken link has been detected will the router use the next odd sequence number as the sequence number for the new routing update that is to be advertised to all its neighbors. Each router maintains an even sequence number to identify the sequence of every routing update. Neighbors will only accept newer routing updates by discarding routing updates with sequence numbers less than the last sequence number heard from the router.

SEAD provides authentication on metrics' lower bounds and senders' identities by using the one-way hash chain. Let H be a hash function and x be a given value. A list of values is computed as follows:

$$h_0, h_1, h_2, \ldots, h_n$$

where $h_0 = x$ and $h_{i+1} = H\ (h_i)$ for $0 \leq i \leq n$. Given any value h_k that has been confirmed to be in the list, to authenticate if a given value d is on the list or not one can compute if d can be derived from h_k by applying H a certain number of times, or if h_k can be derived from d by applying H to d a certain number of times. If either d can be derived from h_k or h_k can be derived from d within a certain number of steps, it is said that d can be authenticated by h_k.

SEAD assumes an upper bound $m - 1$ on the diameter of the ad hoc network, which means that the metric of a routing entry will be less than m. Let $h_0, h_1, h_2, \ldots, h_n$ be a hash chain where $n = m \times k$ and $k \in Z^+$. For an update with the sequence number i and the metric value of j, the value $h_{(k-i)m+j}$ is used to authenticate the routing update entry. By using $h_{(k-i)m+j}$ to authenticate the routing update entry, a node is actually disclosing the value $h_{(k-i)\ m+j}$ and subsequently all h_p where $p \geq (k-i)m + j$, but not any value h_q where $q \leq (k-i)m + j$.

Using a hash value corresponding to the sequence number and metric in a routing update entry allows the authentication of the update and prevents any node from advertising a route to some destination, forging a greater sequence number or a smaller metric. To authenticate the update, a node can use any given earlier authentic hash value h_p from the same hash chain to authenticate the current update with sequence number i and metric j. The current update uses the hash value $h_{(k-i)m+j}$ and $(k-i)$ $m + J \leq P$, thus h_p can be computed from $h_{(k-i)\ m+j}$ by applying H for $(k-i)m + j-p$ times.

The disclosure of $h_{(k-i)m+j}$ does not disclose any value h_q where $q \leq (k-i)m + j$. Let a fake update be advised with a sequence number p and metric q, where $p \geq i$ *and* $q \leq j$, or $q \leq j$. The fake update will need to use the hash value $h_{(k-P)\ m+q}$. If the sequence number p is greater than i or the metric q is less than j, $(k-p)m + q < (k-i)m + j$. This means that a hash value $h_{(k-p)m+q}$ that has not been disclosed is needed to authenticate the update. Since the value $h_{(k-p)m+q}$ has not been disclosed, the malicious node will not be able to have it to fake a routing update.

Ariadne

Ariadne [15] is a secure on-demand routing protocol for ad hoc networks. Ariadne is built on the Dynamic Source Routing protocol (DSR) [16].

Routing in Ariadne is divided into two stages: the route discovery stage and the route maintenance stage. In the route discovery stage, a source node in the ad hoc network tries to find a path to a specific destination node. The discovered path will be used by the source node as the path for all communication from the source node to the destination node until the discovered path becomes invalid. In the route maintenance stage, network nodes identify broken paths that have been found. A node sends a packet along a specified route to some destination. Each node on the route forwards the packet to the next node on the specified route and tries to confirm the delivery of the packet to the next node. If a node fails to receive an acknowledgment from the next node, it will signal the source node using a ROUTE ERROR packet that a broken link has been found. The source node and other nodes on the path can then be advised of the broken link.

The key security features Ariadne adds onto the route discovery and route maintenance are node authentication and data verification for the routing relation packets. Node authentication is the process of verifying the identifiers of nodes that are involved in Ariadne's route discovery and route maintenance, to prevent forging routing packets. In route discovery, a node sends out a ROUTE REQUEST packet to perform a route discovery. When the ROUTE REQUEST packet reaches the destination node, the destination node verifies the originator

identity before responding. Similarly, when the source node receives a ROUTE REPLY packet, which is a response to the ROUTE REQUEST packet, the source node will also authenticate the identity of the sender. The authentication of node identities can be of one of the three methods: TELSA, digital signatures, and Message Authentication Code (MAC).

Data verification is the process of verifying the integrity of the node list in route discovery for the prevention of adding and removing nodes from the node list in a ROUTE RQUEST. To build a full list of nodes for a route to a destination, each node will need to add itself into the node list in the ROUTE REQUEST when it forwards the ROUTE REQUEST to its neighbor. Data verification protects the node list by preventing unauthorized adding of nodes and unauthorized removal of nodes.

6. ARAN

Authenticated Routing for Ad hoc Networks (ARAN) [17] is a routing protocol for ad hoc networks with authentication enabled. It allows routing messages to be authenticated at each node between the source nodes and the destination nodes. The authentication that ARAN has implemented is based on cryptographic certificates.

ARAN requires a trusted certificate server, the public key of which is known to all valid nodes. Keys are assumed to have been established between the trusted certificate server and nodes. For each node to enter into a wireless ad hoc network, it needs to have a certificate issued by the trusted server. The certificate contains the IP address of the node, the public key of the node, a time stamp indicating the issue time of the certification, and the expiration time of the certificate. Because all nodes have the public key of the trusted server, a certificate can be verified by all nodes to check whether it is authentic. With an authentic certificate and the corresponding private key, the node that owns the certificate can authenticate itself using its private key.

To discover a route from a source node to the destination node, the source node sends out a route discovery packet (RDP) to all its neighbors. The RDP is signed by the source node's private key and contains a nonce, a time stamp, and the source node's certificate. The time stamp and the nonce work to prevent replay attacks and flooding of the RDP.

The RDP is then rebroadcast in the network until it reaches the destination. The RDP is rebroadcast with the signature and the certificate of the rebroadcaster. On receiving an RDP, each node will first verify the source's signature and the previous node's signature on the RDP.

On receiving an RDP, the destination sends back a reply packet (REP) along the reverse path to the source after validating the RDP. The REP contains the nonce specified in the RDP and the signature from the destination node.

The REP is unicast along the reverse path. Each node on the path will put its own certificate and its own signature on the RDP before forwarding it to the next node. Each node will also verify the signatures on the RDP. An REP is discarded if one or more invalid signatures are found on the REP.

When the source receives the REP, it will first verify the signatures and then the nonce in the REP. A valid REP indicates that a route has been discovered. The node list on a valid REP suggests an operational path from the source node to the destination node that is found.

As an on-demand protocol, nodes keep track of route status. If there has been no traffic for a route's lifetime or a broken link has been detected, the route will be deactivated. Receiving data on an inactive route will force a node to signal an error state by using an error (ERR) message. The ERR message is signed by the node that produces it and will be forwarded to the source without modification. The ERR message contains a nonce and a time stamp to ensure that the ERR message is fresh.

7. SLSP

Secure Link State Routing Protocol (SLSP) [18] is a secure routing protocol for an ad hoc network building based on link state protocols. SLSP assumes that each node has a public/private key pair and has the capability of signing and verifying digital signatures. Keys are bound with the Medium Access Code and the IP address, allowing neighbors within transmission range to uniquely verify nodes if public keys have been known prior to communication.

In SLSP, each node broadcasts its IP address and the MAC to its neighbor with its signature. Neighbors verify the signature and keep a record of the pairing IP address and the MAC. The Neighbor Lookup Protocol (NLP) of SLSP extracts and retains the MAC and IP address of each network frame received by a node. The extracted information is used to maintain the mapping of MACs and IP addresses.

Nodes using SLSP periodically send out link state updates (LSUs) to advise the state of their network links. LSU packets are limited to propagating within a zone of their origin node, which is specified by the maximum number of hops. To restrict the propagation of LSU packets, each LSU packet contains the *zone radius* and the *hops traversed* fields. Let the maximum hop be R; X, a random number; and H be a hash function. *Zone-radius* will be initialized to $H^R(X)$ and *hops−traversed* be initialized to $H(X)$. Each LSU packet also contains a *TTL* field initialized as $R-1$. If $TTL < 0$ or $H(hops\text{−}traversed) = zone\text{-}radius$, a node will not rebroadcast the LSU packet. Otherwise, the

node will replace the *hops−traversed* field with *H(hops−traversed)* and decrease *TTL* by one. In this way, the hop count is authenticated. SLSP also uses signatures to protect LSU packets. Receiving nodes can verify the authenticity and the integrity of the received LSU packets, thus preventing forging or tampering with LSU packets.

8. KEY ESTABLISHMENT

Because wireless communication is open and the signals are accessible by anyone within the vicinity, it is important for wireless networks to establish trust to guard the access to the networks. Key establishment builds relations between nodes using keys; thus security services, such as authentication, confidentiality, and integrity can be achieved for the communication between these nodes with the help of the established keys.

The dynamically changing topology of wireless networks, the lack of fixed infrastructure of wireless ad hoc and sensor networks, and the limited computation and energy resources of sensor networks, have all added complication to the key establishment process in wireless networks.

Bootstrapping

Bootstrapping is the process by which nodes in a wireless network are made aware of the presence of others in the network. On bootstrapping, a node gets its identifying credentials that can be used in the network the node is trying to join. Upon completion of the bootstrapping, the wireless network should be ready to accept the node as a valid node to join the network.

To enter a network, a node needs to present its identifying credential to show its eligibility to access the network. This process is called *preauthentication*. Once the credentials are accepted, network security associations are established with other nodes.

These network security associations will serve as further proof of authorization in the network. Security associations can be of various forms, including symmetric keys, public key pairs, hash key chains, and so on. The security associations can be used to authenticate nodes. Security associations may expire after a certain period of time and can be revoked if necessary. For example, if a node is suspected of being compromised, its security association will be revoked to prevent the node accessing the network. The actual way of revocation depends on the form of the security associations.

Bootstrapping in Wireless Ad Hoc Networks

Wireless ad hoc networks bring new challenges to the bootstrapping process by their lack of a centralized security infrastructure. It is necessary to build a security infrastructure in the bootstrapping phase. The trust infrastructure should be able to accept nodes with valid credentials to enter the network but stop those nodes without valid credentials from joining the network and establish security association between nodes within the network.

To build such a trust infrastructure, we can use any one of the following three supports: prior knowledge, trusted third parties, or self-organizing capability. Prior knowledge is information that has been set on valid nodes in advance, such as predistributed secrets or preset shared keys. This information can be used to distinguish legitimate nodes from malicious ones. Only nodes with prior knowledge will be accepted to enter the network. For example, the predistributed secrets can be used to authenticate legitimate nodes, so the network can simply reject those nodes without the predistributed secrets so that they can't enter the network.

Trusted third parties can also be used to support the establishment of the trust infrastructure. The trusted third party can be a Certificate Authority (CA), a base station of the wireless network, or any nodes that are designated to be trusted. If trusted third parties are used, all nodes must mutually agree to trust them and derive their trust on others from the trusted third parties. One of the issues with this method is that trusted third parties are required to be available for access by all nodes across the whole network, which is a very strong assumption for wireless networks as well as an impractical requirement.

It is desirable to have a self-organizing capability for building the trust infrastructure for wireless networks, taking into account the dynamically changing topology of wireless ad hoc networks. Implementing a self-organizing capability for building the trust infrastructure often requires an out-of-band authenticated communication channel or special hardware support, such as tamper-proof hardware tokens.

Bootstrapping in Wireless Sensor Networks

Bootstrapping nodes in wireless sensor networks is also challenging for the following reasons:

- *Node capture*. Sensor nodes are normally deployed in an area that is geographically close or inside the monitoring environment, which might not be a closed and confined area under guard. Thus sensor nodes are vulnerable to physical capture because it might be difficult to prevent physical access to the area.
- *Node replication*. Once a sensor node is compromised, it is possible for adversaries to replicate sensor nodes by using the secret acquired from the compromised node. In this case, adversaries can produce fake legitimate node that cannot be distinguished by the network.

- *Scalability*. A single-sensor network may comprise a large number of sensor nodes. The more nodes in a wireless sensor network, the more complicated it is for bootstrapping.
- *Resource limitation*. Sensor nodes normally have extremely limited computation power and memory as well as limited power supply and weak communication capability. This makes some of the deliberate algorithms and methods not applicable to wireless sensor networks. Only those algorithms that require a moderate amount of resources can be implemented in wireless sensor networks.

Bootstrapping a sensor node is achieved using an incremental communication output power level to discover neighbors nearby. The output power level is increased step by step from the minimum level to the maximum level, to send out a HELLO message. This will enable the sensor node to discover neighbors in the order of their distance from the sensor node, from the closest to the farthest away.

Key Management

Key management schemes can be classified according to the way keys are set up (see Figure 15.7). Either keys are managed based on the contribution from all participating nodes in the network or they are managed based on a central node in the network. Thus key management schemes can be divided into contributory key management schemes, in which all nodes work equally together to manage the keys, and distributed key management schemes, in which only one central node is responsible for key management [19].

Classification

The distributed key management scheme can be further divided into symmetric schemes and public key schemes. Symmetric key schemes are based on private key cryptography, whereby shared secrets are used to authenticate legitimate nodes and to provide secure communication between them. The underlying assumption is that the shared secrets are known only to legitimate nodes involved in the interaction. Thus proving the knowledge of the shared secrets is enough to authenticate legitimate nodes. Shared secrets are distributed via secure channels or out-of-band measures. Trust on a node is established if the node has knowledge of a shared secret.

Public key schemes are built on public key cryptography. Keys are constructed in pairs, with a private key and a public key in each pair. Private keys are kept secret by the owners. Public keys are distributed and used to authenticate nodes and to verify credentials. Keys are normally conveyed in certificates for distribution. Certificates are signed by trusted nodes for which the public keys have been known and validated. Trust on the certificates will be derived from the public keys that sign the certificates. Note that given $g^i (mod\ p)$ and $g^j (mod\ p)$, it is hard to compute $g^{i*j} (mod\ p)$ without the knowledge of i and j.

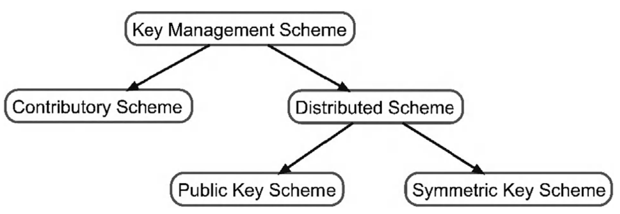

FIGURE 15.7 Key management schemes.

Contributory Schemes

Diffie-Hellman (D-H) [20] is a well-known algorithm for establishing shared secrets. The D-H algorithm's strength depends on the discrete log problem: It is hard to calculate s if given the value g^s (mod p), where p is a large prime number.

Diffie-hellman Key Exchange

D-H was designed for establishing a shared secret between two parties, namely node A and node B. Each party agrees on a large prime number p and a generator g. A and B each choose a random value i and j, respectively. A and B are then exchanged with the public values g^i (mod p) and g^j (mod p). On the reception of g^j (mod p) from B, A is then able to calculate the value $g^{j \times i}$ (mod p). Similarly, B computes $g^{i \times j}$ (mod p). Thus a shared secret, $g^{i \times j}$ (mod p), has been set up between A and B.

9. ING

Ingemarsson, Tang, and Wong (ING) [21] extends the D-F key exchange to a group of n members, $d_1, \ldots, d_n$. All group members are organized in a ring, where each member has a left neighbor and a right neighbor. Node d_i has a right neighbor d_{i-1} and a left neighbor d_{i+1}. Note that for node d_i, its right neighbor is d_{i+1}; for node d_{i+1}, its left neighbor is d_i.

Same as the D-F algorithm, all members in an ING group assume a large prime number p and a generator g. Initially, node d_i will choose a random number r_i. At the first round of key exchange, node d_i will compute $g^{r}{}_{i}$ (mod p) and send it to its left neighbor d_{i+1}. At the same time, node d_i also receives the public value $g^{r}{}_{i-1}$ (mod p) from its right neighbor d_{i-1}. From the second round on,

let q be the value that node d_i received in the previous round, node d_i will compute a new public value $q^{d}{}_{i}$ (mod p). After $n-1$ rounds, the node d_i would have received a public value, g^k (mod p) where $k = \Pi_{m=1}{}^{i-1} r_m \times \Pi_{s=i+1}{}^{n} r_s$, from its right neighbors. With the public value received at the $n-1$th round, the node d_i can raise it to the power of r_i to compute the value g^l (mod p) where $l = \Pi_{m=1}{}^{n} r_m$.

Hypercube and Octopus (H & O)

The Hypercube protocol [22] assumes that there are 2^d nodes joining to establish a shared secret and all nodes are organized as a d-dimensional vector space $GF(2)^d$ Let $b_1, \ldots, b_d$ be the basic of $GF(2)^d$. The hypercube protocol takes d rounds to complete:

- In the first round, every participant $v \in GF(2)^d$ chooses a random number r_v and conducts a D-H key exchange with another participant $v + b_1$, with the random values r_v and r_{v+b1}, respectively.
- In the ith round, every participant $v \in GF(2)^d$ performances a D-H key exchange with the participant $v + b_i$, where both v and $v + b_i$ use the value generated in the previous round as the random number for D-H key exchange.

This algorithm can be explained using a complete binary tree to make it more comprehensible. All the nodes are put in a complete binary tree as leaves, with leaves at the 0−level and the root at the d-level. D-H key exchanges are performed from the leaves up to the root. The key exchange takes d rounds:

- In the first round, each leaf chooses a random number k and performs a D-H key exchange with its sibling leaf, which has a random number j, and the resulting value $g^{k \times j}$ (mod p) is saved as the random value for the parent node of the above two leaves.
- In the ith round, each node at the $i-1$ level performs a D-H key exchange with its sibling node using the random numbers m and n, respectively, that they received in the previous round. The resulting value $g^{m \times n}$ (mod p) is saved as the random value for the parent node of the above two nodes.

After d rounds, the root of the complete binary tree contains the established shared secret*s*. The hypercube protocol assumes that there are 2^d network nodes. The octopus protocol removes the assumption and extends the hypercube protocol to work with an arbitrary number of nodes. Thus the octopus protocol can be used to establish a shared key for a node set containing an arbitrary number of nodes.

Distributed Schemes

A partially distributed threshold CA scheme [23] works with a normal PKI system where a CA exists. The private key of the CA is split and distributed over a set of n server nodes using a *(k,n)* secret-sharing scheme [24]. The *(k,n)* secretsharing scheme allows any k or more server nodes within the n server nodes to work together to reveal the CA's private key. Any set of nodes with fewer than k nodes will not be able to reveal the CA's private key. With the threshold signature scheme [25], any k of the n nodes can cooperate to sign a certificate. Each of the k nodes produces a piece of the signature on the request of signing a given certificate. With all the k pieces of the signature, a valid signature, which is the same as the one produced using the CA's private key, can be produced by combining the k pieces of the signature.

Partially Distributed Threshold CA Scheme

In this way, the partial distributed threshold CA scheme can avoid the bottleneck of the centralized CA of conventional PKI infrastructures. As long as there are at least k of the n nodes available, the network can always issue and sign new certificates. Attacks to any single node will not bring the whole CA down. Only when an attack manages to paralyze $n - k$ or more nodes will the CA's signing service not be available.

To further improve the security of the private key that is distributed over the n nodes, proactive security [26] can be imposed. Proactive security forces the private key shares to be refreshed periodically. Each refreshment will invalidate the previous share held by a node. Attacks on multiple nodes must complete within a refresh period to succeed. To be specific, only when an attack can compromise k or more nodes within a refresh period can the attack succeed.

While conventional PKI systems depend on directories to publish public key certificates, it is suggested that certificates should be disseminated to communication peers when establishing a communication channel with the partial distributed threshold CA scheme. This is due to the fact that the availability of centralized directories cannot be guaranteed in wireless networks. Therefore it is not realistic to assume the availability of a centralized directory.

Self-organized Key Management (PGP-A)

A self-organized key management scheme (PGP-A) [27] has its basis in the Pretty Good Privacy (PGP) [28] scheme. PGP is built based on the "web of trust" model, in which all nodes have equal roles in playing a CA.

Each node generates its own public/private key pair and signs other nodes' public keys if it trusts the nodes. The signed certificates are kept by nodes in their own certificate repositories instead of being published by centralized directories in the X.509 PKI systems [29].

PGP-A treats trust as transitive. So, trust can be derived from a trusted node's trust on another node, that is, if node A trusts node B, and node B trusts node C, then A should also trust C if A knows the fact that node B trusts node C.

To verify a key of a node u, a node j will merge its certificate repository with those of j's trusted nodes, and those of the nodes trusted by j's trusted nodes, and so forth. In this way, node j can build up a web of trust in which node j is at the center of the web and j's directly trusted nodes as node j's neighbors. Node l is linked with node k if node k trusts node l. Node j can search the web of trust built as above to find a path from j to u. If such as path exists, let it be a sequence of nodes S: $node_i$ where $i = 1, \ldots, n$, n be the length of the path, and $node_1 = j$ and $node_n = u$. This means that $node_i$ trust $node_{i+1}$ for all $i = 1, \ldots, n{-}1$. Therefore u can be trusted by j. The path S represents a verifiable chain of certificates. PGP-A does not guarantee that a node u that should be trusted by node j will always be trusted by node j, since there are chances that the node j fails to find a path from node j to node u in the web of trust. This might be due to the reason that node j has not acquired enough certificates from its trusted nodes to cover the path from node j to node u.

Self-Healing Session Key Distribution

The preceding two key management schemes are public key management schemes. The one discussed here, a self-healing session key distribution [30], is a symmetric key management scheme. In such a scheme, keys can be distributed either by an online key distribution server or by key predistribution. A key predistribution scheme normally comprises the key predistribution phase, the shared-key discovery phase, and the path key establishment phase.

In the key predistribution phase, a key pool of a large number of keys is created. Every key can be identified by a unique key identifier. Each network node is given a set of keys from the key pool. The shared-key discovery phase begins when a node tries to communicate with the others. All nodes exchange their key identifiers to find out whether there are any keys shared with others. The shared keys can then be used to establish a secure channel for communication. If no shared key exists, a key path will need to be discovered. The key path is a sequence of nodes with which all adjacent nodes share a key. With the key path, a message can travel from the first node to the last node securely, by which a secure channel can be established between the first node and the last node.

The self-healing session key distribution (S-HEAL) [30] assumes the existence of a group manager and preshared secrets. Keys are distributed from the group manager to group members. Let h be a polynomial, where for a node i, node i knows about $h(i)$. Let K be the group key to be distributed, K is covered by h in the distribution: $f(x) = h(x) + K$. The polynomial $f(x)$ is the information that the group manager sends out to all its group members. For node j, node j will calculate $K = f(j) - h(j)$ to reveal the group key. Without the knowledge of $h(j)$, node j will not be able to recover K.

To enable revocation in S-HEAL, the polynomial $h(x)$ is replaced by a bivariate polynomial $s(x,y)$. The group key is covered by the bivariate polynomial $s(x,y)$ when it is distributed to group members, in the way that $f(N,x) = s(N,x) + K$. Node i must calculate $s(N,i)$ to recover K. The revocation enabled S-HEAL tries to stop revoked nodes to calculate $s(N,i)$, thus preventing them to recover K.

Let s of degree t; then $t + 1$ values are needed to compute $s(x,i)$. Assuming that $s(i,i)$ is predistributed to node i, node i will need another t values to recover $s(N,i)$, namely $s(r_1,x), \ldots, s(r_t,x)$. These values will be disseminating to group members together with the key update. If the group manager wants to revoke node i, the group manager can set one of the values $s(r_1,x), \ldots, s(r_t,x)$ to $s(i,x)$. In this case, node i obtains only t values instead of $t + 1$ values. Therefore, node i will not be able to compute $s(x,i)$, thus it will not be able to recover K. This scheme can only revoke maximum t nodes at the same time.

Now, let's take a very brief look at wireless network security management countermeasures. Security comes at a cost: either in dollars spent on security equipment, in inconvenience and maintenance, or in operating expenses. Some organizations may be willing to accept risk because applying various management countermeasures may exceed financial or other constraints.

10. MANAGEMENT COUNTERMEASURES

Management countermeasures ensure that all critical personnel are properly trained on the use of wireless technology. Network administrators need to be fully aware of the security risks that wireless networks and devices pose. They must work to ensure security policy compliance and to know what steps to take in the event of an attack (see checklist: "An Agenda For Action When Implementing Wireless Network Security Policies").

Management countermeasures for securing wireless networks begin with a comprehensive security policy. A security policy, and compliance therewith, is the

foundation on which other countermeasures (the operational and technical) are rationalized and implemented. Finally, the most important countermeasures are trained and aware users.

11. SUMMARY

Organizations should understand that maintaining a secure wireless network is an ongoing process that requires greater effort than for other networks and systems. Moreover, it is important that organizations more frequently assess risks and test and evaluate system security controls when wireless technologies are deployed. Maintaining a secure wireless network (and associated devices) requires significant effort, resources and vigilance and involves the following steps:

- Maintaining a full understanding of the topology of the wireless network.
- Labeling and keeping inventories of the fielded wireless and handheld devices.
- Creating frequent backups of data.
- Performing periodic security testing and assessment of the wireless network.
- Performing ongoing, randomly timed security audits to monitor and track wireless and handheld devices.
- Applying patches and security enhancements.
- Monitoring the wireless industry for changes to standards to enhance to security features and for the release of new products.
- Vigilantly monitoring wireless technology for new threats and vulnerabilities.

Organizations should not undertake wireless deployment for essential operations until they understand and can acceptably manage and mitigate the risks to their information, system operations, and risk to the continuity of essential operations. As described in this chapter, the risks provided by wireless technologies are considerable. Many current communications protocols and commercial products provide inadequate protection and thus present unacceptable risks to organizational operations. Agencies must proactively address such risks to protect their ability to support essential operations, before deployment. Furthermore, many organizations poorly administer their wireless technologies. Some examples include deploying equipment with factory default settings; failing to control or inventory their access points; not implementing the security capabilities provided; and, not developing or employing a security architecture suitable to the wireless environment (firewalls between wired and wireless systems, blocking unneeded services/ports, using strong cryptography, etc.). To a large extent, most of the risks can be mitigated. However, mitigating these risks requires considerable tradeoffs between technical solutions and costs. Today, the vendor and standards community is aggressively working towards more robust, open, and secure solutions for the near future.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Wireless networks are a general term to refer to various types of networks that communicate without the need of wire lines.
2. True or False? Cellular networks require fixed infrastructures to work.

An Agenda for Action when Implementing Wireless Network Security Policies

The items below are possible actions that organizations should consider; some of the items may not apply to all organizations. A wireless network security policy should be able to do the following (check all tasks completed):

_____**1.** Identify who may use WLAN technology in an organization.
_____**2.** Identify whether Internet access is required.
_____**3.** Describe who can install access points and other wireless equipment.
_____**4.** Provide limitations on the location of and physical security for access points.
_____**5.** Describe the type of information that may be sent over wireless links.
_____**6.** Describe conditions under which wireless devices are allowed.
_____**7.** Define standard security settings for access points.
_____**8.** Describe limitations on how the wireless device may be used, such as location.
_____**9.** Describe the hardware and software configuration of any access device.
_____**10.** Provide guidelines on reporting losses of wireless devices and security incidents.
_____**11.** Provide guidelines on the use of encryption and other security software.
_____**12.** Define the frequency and scope of security assessments.

3. True or False? Wireless ad hoc networks are distributed networks that work without fixed infrastructures and in which each network node is willing to forward network packets for other network nodes.
4. True or False? WEP is designed to protect linkage-level data for wireless transmission by providing confidentiality, access control, and data integrity, to provide secure communication between a mobile device and an access point in a 802.11 wireless LAN.
5. True or False? The WPA standard is aimed at providing a stronger security compared to WEP and is expected to tackle most of the weakness found in WEP.

Multiple Choice

1. Personal deployment of WPA adopts a simpler mechanism, which allows all stations to use the same key. This mechanism is called the:
   A. RC 4 stream cipher
   B. Temporal Key Integrity Protocol (TKIP)
   C. Pre-Shared Key (PSK) mode
   D. Message Integrity Code (MIC)
   E. Extensible Authentication Protocol (EAP) framework
2. What are low-end devices with very limited resources, such as memory, computation power, battery, and network bandwidth:
   A. SPINS
   B. Sequences of intervals
   C. Key usages
   D. Sensor nodes
   E. All of the above
3. Secure Efficient Ad hoc Distance (SEAD) vector routing is a design based on a:
   A. Secure on-demand routing protocol
   B. ROUTE RQUEST
   C. Message Authentication Code (MAC)
   D. Authenticated Routing for Ad hoc Networks (ARAN)
   E. Destination-Sequenced Distance Vector (DSDV) routing
4. What requires a trusted certificate server, where the public key is known to all valid nodes?
   A. ARAN.
   B. RDP.
   C. REP.
   D. ERR.
   E. All of the above.
5. What is a secure routing protocol for an ad hoc network building based on link state protocols?
   A. Neighbor Lookup Protocol (NLP).
   B. Secure Link State Routing Protocol (SLSP).
   C. Bootstrapping protocol.
   D. Preauthentication protocol.
   E. All of the above.

EXERCISE

Problem

What is WEP?

Hands-On Projects

Project

What is a WEP key?

Case Projects

Problem

Organization A is considering implementing a WLAN so that employees may use their laptop computers anywhere within the boundaries of their office building. Before deciding, however, Organization A has its computer security department perform a risk assessment. The security department first identifies WLAN vulnerabilities and threats. The department, assuming that threat-sources will try to exploit WLAN vulnerabilities, determines the overall risk of operating a WLAN and the impact a successful attack would have on Organization A. The manager reads the risk assessment and decides that the residual risk exceeds the benefit the WLAN provides. The manager directs the computer security department to identify additional countermeasures to mitigate residual risk before the system can be implemented. What are those additional countermeasures?

Optional Team Case Project

Problem

Organization C is considering purchasing mobiles devices for its sales force of 300 employees. Before making a decision to purchase the mobiles devices, the computer security department performs a risk assessment. What did the computer security department find out from the risk assessment?

1. INTRODUCTION TO THE WIRELESS SENSOR NETWORK (WSN)

In recent times, advances in microelectronic mechanical systems (MEMS) and wireless communication technologies have led to the proliferation of wireless sensor networks (WSNs). A WSN can be broadly described as a network of nodes that makes a collaborative effort in sensing certain specified data around its periphery and thereby controls the surrounding environment. A typical sensor network consists of a large number of low-cost, low-powered sensor nodes that are deployable in harsh operating environments. Because of their varied applications in civilian and military sectors, WSNs have gained a lot of popularity in the past decade. For instance, applications can include habitat monitoring, air and water quality management, hazard and disaster monitoring, health care, remote sensing, smart homes, and so on. Figure 16.1 depicts a usual wireless sensor network in which sensor nodes are distributed in an ad-hoc, decentralized fashion. Usually, WSNs are connected to a legacy network (IP network or 3 G network) using one or more sink nodes or base stations. Furthermore, routing in WSN is typically carried in a hop-by-hop fashion.

In general, WSN protocols should be designed to minimize energy consumption and preserve the life of the network. Information gathering in WSN is done by asking for information regarding a specific attribute of the phenomena or by asking for statistics about a specific area of the sensor field. This requires a protocol that can handle requests for a specific type of information, which includes datacentric routing and data aggregation. The last important characteristic of wireless sensor networks is that the position of the nodes may not be engineered or predetermined, and therefore, must provide data routes that are self-organizing.

Although WSNs have gained a lot of popularity, they present some serious limitations when one is implementing security. WSNs present extreme resource limitations in available storage (memory) space, computing, battery life, and bandwidth. Hence, sensor networks present major challenges for integrating traditional security techniques in such resource-constraint networks. In addition, the ad-hoc, decentralized nature of WSNs would pose even greater challenges in applying conventional security mechanisms. Hence, researchers face the challenge of taking all these constraints in consideration while providing adequate security to such sensor networks.

WSN Architecture and Protocol Stack

Most of the traditional networks (for example, IP networks) are built on the Open System Interconnection (OSI) model. However, WSNs operate in a resource-constrained environment and therefore deviate from the traditional OSI model. A WSN stack usually consists of six layers: an application layer, middleware, transport, network, data link, and physical layer. In addition to these six layers that are mapped to each sensor node, there are three more planes that span across the entire sensor network and have more visibility to address issues such as mobility, power, and task management (see Figure 16.2).

Application Layer

The application layer aims to create an abstraction of the main functions of the sensing application, thereby making the lower software and hardware levels transparent to the end user. The application layer involves several processes running simultaneously and handles user requests relating to data aggregation, location finding, sleep/awake cycle control, time synchronization, authentication, encryption, key distribution, and other security measures. It also defines the order and format of message exchange between the two communication parties.

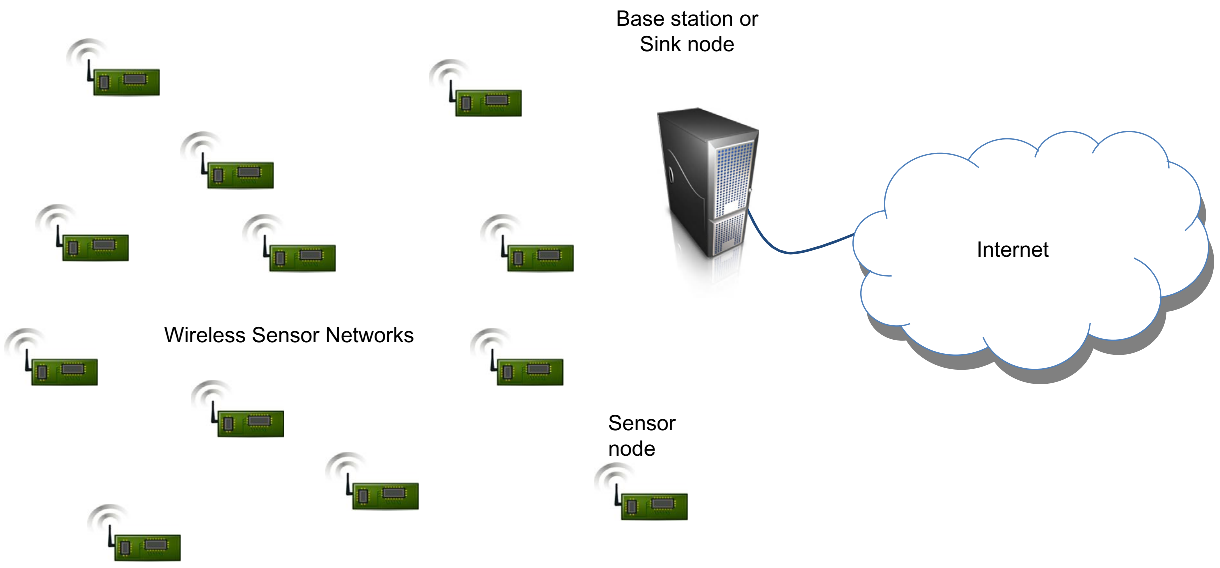

FIGURE 16.1 Wireless sensor network.

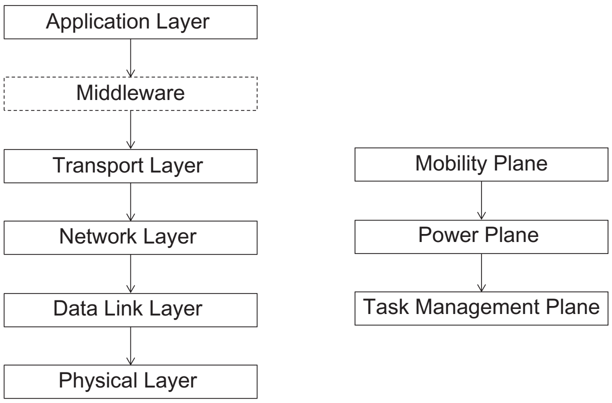

FIGURE 16.2 WSN protocol stack.

Middleware

The middle layer provides an application programming interface (API) for applications existing in the upper layers. It also may involve complex functionalities such as resource sharing and task management.

Transport Layer

The transport layer is responsible for flow and congestion control. It also performs error control to detect corrupted frames that arrive from lower layers. Due to the severe operating environment and reduced transmission power, it is difficult to achieve high end-to-end link reliability compared to traditional wireless networks. In addition, the transport layer performs fragmentation of sender data and reassembly of received data frames.

Network Layer

The network layer's primary goals are to perform routing operations and self-configuration. It is responsible for link failures and provides regular updates to neighboring nodes. However, assuring network connectivity at all times is a major challenge due to dynamically changing network topology. The routing protocols in WSN are very different from traditional routing protocols because of the need to optimize network life by performing intelligent routing.

Data Link Layer

The data link layer is an interface between the network and physical layer. It is further subdivided into two modules: Medium Access Control (MAC) and Logical Link Control (LLC). The MAC module plays a critical role in conserving network life by efficiently allocating medium access to the contending nodes. The LLC is on top of the MAC layer and is responsible for cyclic redundancy check (CRC), sequencing information, and addition of appropriate source and destination information. The data link layer is also responsible for the multiplexing of data streams and data frame detection. So, with the preceding in mind: first create a network infrastructure, which includes establishing communication links between possibly thousands of nodes, and provides the network self-organizing capabilities. Second, the data link layer can fairly and efficiently share communication resources between all the nodes.

Physical Layer

The physical layer is responsible for converting digital bits into analog symbols and vice versa. It involves

modulation and demodulation, frequency selection, power control, and symbol synchronization. WSNs usually operate in frequencies ranging from 915 MHz to 2.4 GHz. It is recommended using a lower-frequency band, as there is higher attenuation when operating in higher-frequency bands. However, with the limited availability of the bandwidth in the lower frequencies, the WSN is forced to operate at higher frequencies. The environment in which sensors are operating plays a major role in signal attenuation. Thus, sensors placed on the ground or floating on water experience greater attenuation and consequently require higher transmit power. The choice of modulation scheme is one of the prime factors in deciding the transmit power. The modulation scheme decides the bit error rate (BER), spectrum efficiency, and number of bits per symbol. For example, an M-ary modulation scheme is able to transmit more bits per symbol than other binary modulation schemes such as Phase Shift Keying (PSK). However, M-ary schemes result in higher BERs and require more transmit power than the binary modulation schemes. Hence binary modulation schemes are more applicable to WSN.

Mobility Plane

Sensor nodes can be fixed on moving objects such as animals, vehicles, and people, which will lead to a dynamic topology. In the event of some mobility by sensor nodes, the mobility in collaboration with the network layer is responsible for maintaining the list of active neighboring nodes. It is also responsible for interacting periodically with the mobility planes of other neighboring nodes, so that it can create and maintain a table of active, power-efficient routes.

Power Plane

The power plane focuses on the awareness of power at each horizontal and vertical layer. It is responsible for shutting off the sensors if they are not participating in any routing decisions or simply if the sensing activity is complete. The power planes of each node work collectively on deciding efficient routes to sink nodes and maintain the sleep/awake cycles of sensor nodes.

Task Management Plane

The task management plane is responsible for achieving a common goal. The goal is met by taking the properties of each layer and across each layer in a power-aware manner.

Vulnerabilities and Attacks on WSN

A taxonomy allows organizations to reason about attacks at a level higher than a simple list of vulnerabilities (see Figure 16.3). It provides a classification system that ideally suggests ways to mitigate attacks by prevention, detection, and recovery.

In general, attacks can be divided into active and passive attacks:

Passive Attack

In this type of attack, the attacker is able to intercept and monitor data between communicating nodes, but does not tamper or modify packets for fear of raising suspicion of malicious activity among the nodes. For example, in traffic analysis, the attacker may not be able to decode encrypted data, but can find useful information by analyzing headers of packets, their sizes, and the frequency of transmission. In WSN, reconnaissance can also be performed to understand information exchange between communicating nodes, particularly at data aggregation points. Furthermore, routing information can be exploited using traffic analysis.

Active Attack

In this type of attack, the attacker actively participates in all forms of communication (control and data) and may modify, delete, reorder, and replay messages or even send spoofed illicit messages to nodes in the network. Some other active attacks include node capturing, tampering with routing information, and resource exhaustion attacks. Peculiar to WSN, the attacker can modify the

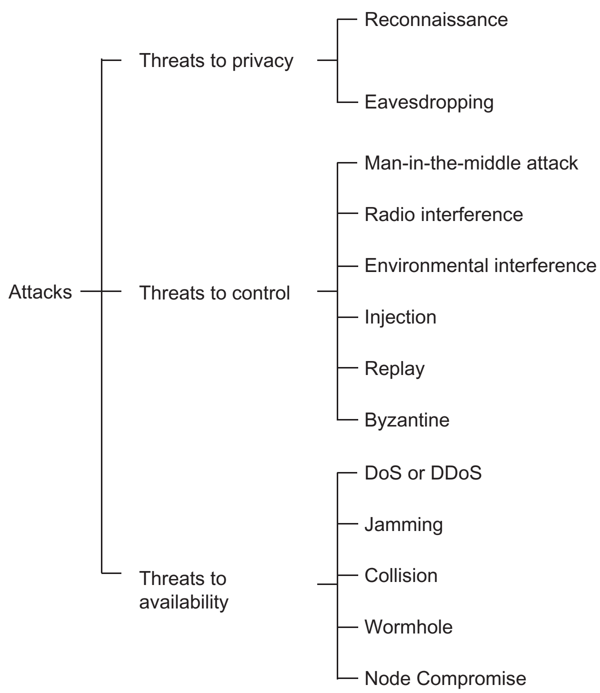

FIGURE 16.3 Taxonomy of attacks for WSN.

environment surrounding sensors, which could affect the sensed phenomena.

2. THREATS TO PRIVACY

In WSN, threats to privacy can be further classified into reconnaissance and eavesdropping.

Reconnaissance

Reconnaissance refers to intelligence gathering or probing to access the vulnerabilities in a network in order to launch a full-scale attack later. Reconnaissance attacks can be further classified into active and passive. Passive reconnaissance attacks include the collection of network information through indirect or direct methods, but without probing the target; active reconnaissance attacks involve the process of gathering traffic with the intention of eliciting responses from the target.

Eavesdropping

Eavesdropping is the act of listening secretly to a private conversation. However, in the paradigm of WSN, eavesdropping is an operation to learn the "aggregate data" that is being collected by the entire network. Hence, eavesdropping between two specific sensor nodes may not help the attacker in thoroughly understanding the entire network. It can be further classified into *active* and *passive* eavesdropping:

- *Active eavesdropping:* In this case, the adversary actively sends queries to other nodes in an attempt to goad them to respond to his queries, and in exchange will be able to comprehend the precise task assigned to the nodes in the network. Usually, the attacker launches a "man-in-the-middle attack" (discussed below) to infiltrate the network and enforce himself on the active path.
- *Passive eavesdropping:* The attacker inserts him- or herself into the active path, unbeknownst to other nodes in the network. He or she then passively listens to all traffic sent over the broadcast medium. It may be difficult to detect a passive eavesdropping attack, as the attacker may be operating in a stealth mode.

Threats to Control

The nodes in the network are unaware that the entire flow control is being handled by the attacker.

Man-in-the-Middle Attack

The man-in-the-middle attack is one of the classical attacks that can be executed in a WSN environment. In this type of attack, the attacker intrudes into the network and attempts to establish an independent connection between a set of nodes and the sink node. He can be in either a passive or an active state. In a passive state, he simply relays every message among the nodes with the intention of performing an eavesdropping attack. In an active state, he can tamper with the intercepted data in an effort to break authentication. In addition, the attack can be executed at the physical, data link, network, and application layers [1].

Radio Interference

With the increase in the number of wireless technologies using the same open spectrum band (2.4 GHz, 5 GHz, or 900 MHz), there is bound to be radio interference. For example, in a dense urban environment, where cordless phones share the same spectrum, radio interference can cause a sharp degradation of individual node performance. Similar problems can be projected for sensor networks with the increase in sensor nodes per network. The result of such interference could lead to change in the information bits transmitted over the wireless medium, thereby making the bits unintelligible and ultimately being dropped by the receiver [2]. Hence, radio interference could lead to a denial-of-service attack. The worst-case scenario in radio interference is jamming.

Injection Attack

After the attacker has clandestinely intruded into the WSN network, he may impersonate a few of the sensor nodes (or even sink nodes) and may inject malicious data into the network. The malicious data might be false advertisement of neighbor-node information to other nodes, leading to impersonation of sink nodes and aggregation of all data.

Replay Attack

A replay attack is a common attack in WSN, whereby an attacker is able to intercept user data and retransmit user data at a later time. This attack is particularly useful in breaking weak authentication schemes, which do not consider the time stamp when authenticating nodes. This attack is also useful during shared key-distribution processes.

Byzantine Attack

In a Byzantine attack, the outside adversary is able to take full control of a subset of authenticated nodes that can be further used to attack the network from inside. Such attacks by malicious behavior are known as Byzantine attacks. Some examples of Byzantine attacks

are black holes, flood rushing, wormholes, and overlay network wormholes:

- *Black-hole attack*: In this type of attack, the attacker drops packets selectively, or all control and data packets that are routed through him. Therefore, any packet routed through this intermediate malicious node will suffer from partial or total data loss.
- *Flood rushing attack*: This type of attack is common to wireless networks and exploits the flood duplicate suppression technique. In this attack, the attacker attempts to overthrow the existing routing path by sending a flood of packets through an alternate route, which will result in discarding the legitimate route and adopting the adversarial route. Usual authentication schemes cannot prevent this attack, as the adversaries are authenticated nodes.
- *Wormhole attack:* In this type of attack, two conniving sensor nodes, or laptops, tunnel control and data packets between each other, with the intention of creating a shortcut in the WSN. Such a low-latency tunnel between the two conniving nodes will likely increase the probability of it being selected as an active path. This type of attack is very closely related to the sinkhole attack, because one of the conniving nodes could falsely advertise to be the sink node and thereby attract more traffic than usual. One of the main differences between a Byzantine wormhole and a traditional wormhole is that in a Byzantine wormhole, the tunnel exists between two compromised nodes, while in a traditional wormhole, two legitimate nodes are tricked into believing that a secure tunnel exists between them.
- *Byzantine overlay network wormhole attack:* This type of attack is a variant of the wormhole attack and occurs when the wormhole attack is extended to multiple sensor nodes; resulting in an overlay of compromised nodes. It provides a false illusion, to honest nodes, that they are surrounded by legitimate nodes, resulting in frequent reuse of the adversarial path.

Sybil Attack

The Sybil attack was first introduced by John R. Douceur while studying security in peer-to-peer networks [3], and later Karlof and Wagner showed that this type of attack poses a serious threat to routing mechanisms in WSN [4]. Sybil is an impersonation attack in which a malicious node masquerades as a set of nodes by claiming false identities, or generating new identities in the worst case [5]. Such attacks can be easily executed in a WSN environment because the nodes are invariably deployed in an unstructured and distributed environment, and communicate via radio transmission. They are especially detrimental in applications such as data aggregation, voting systems, reputation evaluation, and geographic routing. By using a Sybil attack in location-aware routing, it is possible to be in multiple locations at the same time.

Sinkhole Attack

In a sinkhole attack, the adversary impersonates a sink node and attracts the whole of traffic to a node or a set of nodes. Similar to a black-hole attack, the attacker takes control of a few compromised nodes and advertises false routing information to its neighbors, thereby luring all traffic to him.

Threats to Availability

Due to threats to the WSN, some portion of the network or some of the functionalities or services provided by the network could be damaged and unavailable to the participants of the network. For instance, some sensors could die earlier than their expected lifetimes. Thus, availability service ensures that the necessary functionalities or the services provided by the WSN are always carried out, even in the case of attacks.

Denial of Service (DoS) or DDoS

A denial-of-service attack occurs when an attacker floods the victim with bogus or spoofed packets with the intent of lowering the victim's response rate. In the worst-case scenario, it makes the victim totally unresponsive. For instance, in a WSN environment where nodes have limited computational capacity, a DoS attack from a resource-abundant adversary can overwhelm the nodes by flooding packets, which will exhaust communication bandwidth, memory, and processing power. From an attacker's point of view, this attack is also useful in wireless networks where nodes are required to deliver time-critical data. Jamming the wireless links can also lead to a DoS attack. An extension of a DoS attack is a distributed DoS attack, where an attacker takes control of a few nodes in the network, leading to a distributed flood attack against the victim.

HELLO Flood Attack

One of the common techniques for discovering neighbors is to send HELLO packets. If a node receives a HELLO packet, it indicates that it is within the range of communication. However, a laptop-class adversary could easily send HELLO packets with sufficient power to convince the sensor nodes that it is in proximity of communication and may be a potential neighbor. The adversary could also impersonate a sink node or a cluster node.

Jamming

Jamming is one of the most lethal types of attacks in WSN and is a direct way to compromise the entire wireless network. In this type of attack, the attacker jams a spectrum band with a powerful transmitter and prevents any member of the network in the affected area from transmitting or receiving any packet. Jamming attacks can be divided into constant jamming and sporadic jamming. Sporadic jamming can be very effective at times when a change in one bit of a data frame will force the receiver to drop it. In this kind of attack, it is difficult for the victim to identify whether his band is being jammed intentionally or due to channel interference; his immediate reaction is usually to increase his transmitting power, thereby depleting resources at a faster rate. Jamming attacks target the physical and MAC layers. Four types of jamming attacks (random, reactive, deceptive, and constant) would result in DoS attacks [6]. Xu et al. conclude that intrusion detection schemes can be very complex with reference to differentiating malicious attacks from link impairment.

Collision

Collision attacks target the MAC layer to create costly exponential backoff. Whenever collision occurs, the nodes should retransmit packets affected by collision, thus leading to multiple retransmissions. The amount of energy expended by the attacker is much less than the energy expended (battery exhaustion) by the sensor nodes. Collision attacks can be categorized under resource exhaustion attacks.

Node Compromise

Node compromise is one of the most common and detrimental attacks in WSN. As sensors can be deployed in harsh environments such as a battlefield, ocean bed, or the edge of an active volcano, they are easily susceptible to capture by a foreign agent. In the case of a battlefield scenario, the enemy could make an effort to dig into nodes with the intention of extracting useful data (extracting private keys in sensor nodes). Furthermore, it could be reprogrammed and launched into a battlefield to operate on behalf of the enemy.

Attacks Specific to WSN

Wireless sensor networks are vulnerable to eavesdropping problems as the data transmission highly depends on the assumption that the receiving node faithfully receives and forwards the same transmitted packet containing specified parameters. But during peer-to-peer communication the parameters may be spoofed, replaced, altered, repeated, or even diminished by the single frequency or intentional intruders who can easily analyze the traffic flow and fabricate new parameters containing wrong information and transmit them to the sink nodes.

Attacks on Beaconing Protocol

A beaconing protocol uses a breadth-first spanning tree algorithm to broadcast routing updates. The sink node periodically broadcasts updated routing information to its immediate neighboring nodes. These neighboring nodes then rebroadcast this information to their immediate neighbors, and the process continues recursively. During this process, each intermediate node makes a note of its parent node (the parent node is the first node that was able to make contact with its subordinate node and relay the routing information). When all the active nodes are operational, they should send all the sensed data to their parent node. However, this protocol is vulnerable to many attacks. For example, a simple impersonation attack, leading to a sinkhole attack, can totally compromise the entire network [4,7].

Authentication can be used to prevent such impersonation attacks, but it does not prevent a laptop-class adversary from launching a selective forwarding attack, an eavesdropping attack, or a black-hole attack. The attacker creates a wormhole between two conniving laptop-class adversaries. The two laptops are placed near the sink node and the targeted area, respectively. The laptop near the sink node attracts its entire neighbor's traffic and simply tunnels these authenticated messages to its colluder. The laptop attacker, close to the sink node, plays a passive role in forwarding these messages. Due to his furtive nature, it is difficult for his neighbors to detect whether he is malicious. Once the authenticated messages reach the remote laptop adversary, he could launch a black-hole attack or a selective forwarding attack.

Let us consider a situation in which digital signatures are being used for authentication and, while the routing updates are in progress, the sink node's private key is leaked. As soon as the sink node realizes that its private key is being compromised, it immediately broadcasts a new public key. All the nodes in close proximity to the sink node will update their local copy of the sink node's public key. The laptop close to the sink node will perform the same operation and convey this information to its colluding laptop. The remote laptop can now easily impersonate the sink node and launch a sinkhole attack. In addition, she can further create routing loops, which is a resource-exhaustion attack.

Attacks on Geographic- and Energy-Aware Routing (GEAR)

GEAR proposes a location- and energy-aware, recursive routing algorithm to address the problem of uneven energy consumption in routing in WSN. In GEAR, every node gauges the energy levels of its neighbors along with the distance from the target before making a routing decision. In such situations, a laptop-class attacker can advertise that he has larger energy levels than his neighboring node and attract all traffic to him. Thenceforth, he can execute a Sybil, black-hole, or selective forwarding attack.

As attacks on WSN become more sophisticated, the demand for new security solutions is continually increasing. Hence, an array of new security schemes have been designed and implemented in the past decade [8,9]. Most of these schemes have been designed to provide solutions on a layer-by-layer basis rather than on a per-attack basis; in doing so, they have left a gap between layers that may lead to cross-layer attacks.

In general, any security suite should ensure authentication, integrity, confidentiality, availability, access control, and nonrepudiation (see checklist: An Agenda for Action When Implementing a Security Suite). In addition, physical safety is absolutely necessary to avoid tampering or destruction of nodes.

Security in WSN Using a Layered Approach

Most researchers have come up with a security solution to WSN based on a layered approach. However, a layered approach has noticeable flaws such as redundant security or inflexible security solutions.

Security Measures in the Physical Layer

To prevent radio interference or jamming, the two common techniques used are frequency-hopping spread spectrum (FHSS) and direct-sequence spread spectrum (DSSS). In FHSS, the signal is modulated at frequencies such that it hops from one frequency to another in a random fashion at a fixed time interval. The transmitter and the corresponding receiver hop between frequencies using the same pseudorandom code for modulation and demodulation. If an eavesdropper intercepts a FHSS signal, unless she has prior knowledge of the spreading signal code, she will not be able to demodulate the signal. Furthermore, spreading the signal across multiple frequencies will considerably reduce interference.

In DSSS, a spreading code is used to map each data bit in the original signal to multiple bits in the transmitted signal. The pseudorandom code (spreading code) spreads the input data across a wider frequency range compared

An Agenda for Action when Implementing a Security Suite

A construction of tamper-resistant sensor nodes is absolutely necessary. However, such tamper-resistant schemes come at a higher manufacturing cost and are restricted to applications that are not only critical, but use fewer nodes; they should be able to do the following when implementing a security suite (check all tasks completed):

_____**1.** *Authentication:* The main objective of authentication is to prevent impersonation attacks. Hence, authentication can be defined as the process of assuring that the identity of the communicating entity is what it claims to be.

_____**2.** *Integrity:* The goal of integrity is to affirm that the data received is not altered by an interceptor during communication (by insertion, deletion, or replay of data) and is exactly as it was sent by the authorized sender. Usually, cryptographic methods such as digital signatures and hash values are used to provide data integrity.

_____**3.** *Confidentiality:* The goal of confidentiality is to protect the data from unauthorized disclosure. A common approach to achieving confidentiality is to encrypt user data.

_____**4.** *Availability:* The goal of availability is to ensure that the system (network) resources are available and usable by an authorized entity, upon its request. It tries to achieve survivability of the network at all times.

_____**5.** *Access control:* The goal of access control is to enforce access rights to all resources in its system. It tries to prevent unauthorized use of system and network resources. Access control is closely related to authentication attributes. It plays a major role in preventing leakage of information during a node-compromise attack. One of the conventional approaches to access control is to use threshold cryptography. This approach hides data by splitting it into a number of shares. To retrieve the final data, each share should be received through an authenticated process.

_____**6.** *Nonrepudiation:* Nonrepudiation can be best explained with an example. Let Alice and Bob be two nodes, who wish to communicate with each other. Let Alice send a message (M) to Bob. Later, Alice claims that she did not send any message to Bob. Hence, the question that arises is how Bob should be protected if Alice denies any involvement in any form of communication with Bob. Nonrepudiation aims to achieve protection against communicating entities that deny that they ever participated in any sort of communication with the victim.

to the input frequency. In the frequency domain, the output signals appear as noise. Since the pseudorandom code provides a wide bandwidth to the input data, it allows the signal power to drop down below the noise threshold without losing any information. Therefore, this technique is hard for an eavesdropper to detect, due to lower energy levels per frequency and more tolerance to interference. The above-mentioned schemes can provide security only as long as the hopping pattern or the spreading code is not disclosed to any adversary.

Security Measures in the Data Link Layer

Link-layer security plays an important role in providing hop-by-hop security. Its protocols are useful in handling fair channel access, neighbor-node discovery, and frame error control. Legacy security protocols such as Secure Socket Layer (SSL) or Internet Protocol Security (IPSec) cannot be applied directly to WSN because they do not provide data aggregation or allow in-network processing, which are prime requirements in designing security protocols.

To prevent denial-of-service (DoS) attacks on WSN, it is proposed that each intermediate node in the active routing path perform an authentication and integrity check. However, if a few intermediate nodes in the active path have very low energy levels, and if they are forced to perform authentication checks, they will expend all their energy and disrupt the active path. On the other hand, if we look at end-to-end authentication in WSN, it is more energy-efficient, since the sink node (resource-abundant) is the only node that performs authentication and integrity checks. Nevertheless, this scheme is vulnerable to many types of security attacks (black hole, selective forwarding, and eavesdropping). Hence there is a need for adaptive schemes that consider the energy levels of each node when deciding on the authentication schemes.

Early security approaches focused on symmetric keying techniques, and authentication was achieved using Message Authentication Code (MAC). One of the common MAC schemes is a cipher-block chaining message authentication code. However, this scheme is not secure for variable-length input messages. Hence the end user (sensor nodes) has to pad the input messages to be equal to a multiple of the block cipher. Therefore, each node has to waste energy, padding input data. To overcome this issue, other block cipher models such as CTR and OCB have been proposed. With reference to confidentiality, symmetric encryption schemes used to protect WSN are DES, AES, RC5, and Skipjack (block ciphers) and RC4 (a stream cipher). Usually, block ciphers are preferred to stream ciphers because they allow authentication and encryption.

A few proposed link-layer security frameworks include TinySec, Sensec, SNEP, MiniSec, SecureSense [9,10], and ZigBee Alliance [11]. However, these schemes have limitations. For example, in TinySec a single key is manually programmed into all the sensor nodes in the network. A simple node-capture attack on any one of these nodes may result in the leakage of the secret key and the compromising of the entire network. A stronger keying mechanism is needed to secure TinySec. In addition, TinySec requires padding for input messages that are less than 8 bytes. It uses block cipher to encrypt messages, and for messages that are less than 8 bytes, the node will have to use extra energy to pad the message before encrypting.

3. SECURITY MEASURES FOR WSN

In all WSN applications, authentication and further encryption are fundamental security requirements and are useful in mitigating impersonation attacks. They are also useful in preventing the ever-increasing DoS and DDoS attacks on limited resource-constraint environments such as WSN.

Authentication

Three scenarios exist in WSN that require authenticated communication:

- Sink node to sensor nodes and vice versa
- Sensor node with other sensor nodes
- Outside user and sensor nodes

Most of the time critical applications in WSN require a message to be sent as promptly as possible. The intermediate nodes between the sender and receiver are responsible for relaying the message to the receiver. If one of the nodes is compromised, the malicious node can inject falsified packets into the network while routing messages. Such an act could lead to falsified distribution of such messages and, in turn, deplete the energy levels of other honest nodes. Hence, there is a need to filter messages as early as possible by authenticating every message, consequently conserving relaying energy.

In most WSN applications, the sensor nodes are expected to aggregate, process, store, and supply sensed data upon the end user's query. For example, in a military application, soldiers would require constant interaction with motion sensors that detect any movement along the border. In such situations, a large number of mobile or static end users could query the sensor nodes for sensed data. Usually, such interactions are realized through broadcast/multicast operations. Therefore, in such situations, a broadcast authentication mechanism is required before the query is sent. Furthermore, access control is also required, which would only allow the authorized user to access data to which he is entitled. Broadcast

authentication was first addressed in μTESLA [9]. In this scheme, users are assumed to be a few trustworthy sink nodes. This scheme uses one-way hash functions, and the hash pre-images are used as keys to the Message Authentication Code (MAC) algorithm.

However, the messages are transmitted through a wireless medium, which consumes a considerable amount of time. In addition, the hop-by-hop routing nature of WSN further creates a delay in transmission. Hence, there is an increased need for rapid generation and verification of signature schemes.

The existing symmetric schemes such as μTESLA and its variants use Message Authentication Code (MAC) to gain efficiency in terms of processing and energy consumption. However, these symmetric schemes suffer from delayed authentication and sluggish performance for large-scale networks, and they are susceptible to DoS attacks due to late authentication. Furthermore, multiple senders cannot send authenticated broadcast messages simultaneously. For example, if a single node is interested in broadcasting a message, it would have to send a Unicast message to its respective sink node, which would then broadcast the message to all the other nodes on its behalf. Because of resource constraint, asymmetric schemes—for example, digital signatures that would require public key certificates—were pronounced inefficient. Hence, to address this problem, new avenues are being explored to introduce authentication in public-key cryptography in WSN [12].

Lightweight Private Key Infrastructure (PKI) for WSN

Although the applicability of PKI-based approaches has been deemed inappropriate for a resource-constraint environment such as WSN, security researchers have been proposing new lightweight PKI-based approaches for WSN. For instance, a simplified version of Secure Socket Layer (SSL) has been proposed in WSN [13]. Although this SSL version has a smaller overhead when compared to the usual SSL/TLS protocol, it is still not directly applicable to mobile sensor nodes because it would lead to increased communication and computational overhead. For instance, in an ad-hoc mobile sensor network, the nodes keep changing their location, and any change in their position would compel them to initiate the SSL protocol before informing their neighbors of their new location. In addition, schemes such as TinyPK have been designed that are in conjunction with TinySec and facilitate authentication and key agreement between sensor nodes [14]. However, TinyPK implements the Diffie-Hellman key-exchange protocol, which is susceptible to an active man-in-the-middle attack. Huang et al. [15] proposed a hybrid architecture for authenticated key establishment of a session key between a leaf node and a sink node or an end user. This protocol leverages on the difference in the computational and communication capabilities between the leaf node and the resource-abundant device (sink node or end user). During the inception of the protocol, both parties exchange certificates issued by a certificate authority (CA) to extract each other's public keys. However, the corresponding private keys are discovered after both parties run the protocol. This step in this protocol can easily be exploited by an adversary by replaying a valid certificate that would result in a DoS attack. As a result, the nodes are forced to perform expensive computations and waste their resources and bandwidth. In addition, [16] showed a serious vulnerability in Huang et al.'s scheme wherein an end user can easily discover the long-term private key of a leaf node after having one normal run of the protocol.

To expunge the transmission of public key certificates, Ren, Lou, and Zhang [17] propose a Hybrid Authentication Scheme (HAS) for a multiuser broadcast authentication scheme in WSN. In this scheme, each sensor node is preloaded with the required public key information of the end user using the Bloom filter and Merkle hash tree [18,19]. However, HAS with the Merkle hash tree does not facilitate user scalability (a new user can only be added into the network after revocation of the old user).

Key Management in WSN

Recent advances in Integrated Circuit (IC) fabrication have led to the proliferation of wireless sensor networks, which comprise low-cost sensors with limited storage and processing power. WSNs have applicability in diverse fields, such as military, ocean, and wildlife monitoring; earthquake monitoring; safety monitoring in buildings; and in new smart home technology proposed by 4 G technologies. However, such networks deviate from the legacy-embedded wireless networks in terms of scalability, dynamic nature with regard to the addition or deletion of nodes, and deployment areas. Hence, there is a greater challenge in providing security by taking such harsh operational requirements into consideration. One such challenge is in the area of key distribution and its management. In addition, the lack of a-priori information about the topology of WSN makes key management fairly complex. Key distribution provides communication secrecy (confidentiality) and authentication among sensor nodes, and key revocation refers to the task of removing compromised keys from the network. Key distribution can be further divided into symmetric and asymmetric key-distribution protocols.

In recent years, considerable work has been done in proposing new symmetric key-distribution protocols in WSN, but less effort has been invested in the area of asymmetric key-distribution algorithms in WSN, which have low computational and storage requirements. Of late, significant work has been done to show the applicability of implementing binary-field algorithms on sensor nodes [20]. Consequently, such implementations have resulted in considerable reductions in computational time and memory access.

In general, key-distribution schemes in WSN can be broadly classified into four classes: symmetric key algorithms, trusted server mechanisms, random key-predistribution schemes, and public key algorithms. Later in this chapter, we review a few existing key-distribution schemes in WSN.

Symmetric Key Algorithms

In this class, a single shared key is used to perform the encryption and decryption operations in a communication network.

Fully Pairwise-Shared Keys

In this scheme, every node in the network shares a unique, preshared, symmetric key with every other node in the network. The keys are preloaded into the sensor nodes before deployment. Hence, in a network of n nodes, there would be a total of $n(n-1)/2$ unique keys. Subsequently, every node stores $n-1$ keys, one for each of the other nodes in the network. In this class of protocols, the compromise of a few sensor nodes will not result in the complete collapse of the entire network. However, the applicability of this approach in large sensor networks is not pragmatic, as each node would need to store $n-1$ keys, thus resulting in the rapid exhaustion of its limited memory space. In addition, nodes usually communicate with their immediate one-hop neighbors, thereby eliminating the need to establish unique keys with every node in the network. Although symmetric key algorithms are limited in terms of key distribution, they provide basic cryptographic primitives, which can be used in combination with asymmetric key cryptographic algorithms.

Trusted Server Mechanisms

In this category, key distribution is done via centralized trusted servers, which are usually static in nature. In WSN, the sink node or the base station can act as a key-distribution center (KDC). Usually, unique symmetric keys are shared between the sink node and the ordinary nodes. If two nodes were to communicate with each other, they would first authenticate with the base station, after which the base station generates a link key and sends it securely to both parties.

An example of a base-station-mediated key-agreement protocol is the Security Protocol for Sensor Networks: SPINS [9]. Using this protocol, one can preload only one unique single key in every node of the network. Hence, a node capture will not result in the total compromise of the network. In addition, centralized revocation is possible through authenticated unicasts from the trusted base station. The main drawback of this scheme is that the trusted base station represents a single point of compromise for security information, and may also induce a focused communication load centered on the base station, which may lead to early battery exhaustion for the nodes closest to the base station. Another concern is that certain networks do not have a suitable, highly functional, and tamper-proof device that can be used as a secure KDC.

λ-Secure $n \times n$ Key-Establishment Schemes

Now let's address the problem of key distribution and key establishment [21,22] between all pairs of n principals. Although these schemes were originally intended for group keying in traditional networks, and not for sensor networks, they are included here because of their relevance to the development of subsequent key-distribution schemes for sensor networks. The schemes of both Blom and Blundo et al. have an important resiliency property—the λ-secure property: The coalition of no more than λ-compromised sensor nodes reveals nothing about the pairwise key between any two noncompromised nodes.

The main advantage of this class of schemes is that they allow a parameterizable trade-off between security and memory overhead. Whereas the full pairwise scheme involves the storage of $O(n)$ keys at each node and is n-secure, this class of schemes allows the storage of $O(\lambda)$ keys in return for a λ-secure property, and it is perfectly resilient to node compromise until $\lambda + 1$ nodes have been compromised, at which point the entire network's communications are compromised.

Random Key-Predistribution Schemes

In this method, keys are predistributed by preloading random keying material on sensor nodes with the intention of establishing a common secret key between the communicating entities. Upon deployment, these nodes carry out a lookup process to see if a shared key exists between them. As keys are preloaded in a random manner, a certain set of nodes may not share a common key with each other. In such cases, nodes could make use of their immediate neighbors who share keys as bridges between the nodes that do not share a common key. One of the early

key-sharing algorithms using random graph theory was proposed by Eschenauer and Gligor [23].

Basic Random Key-Predistribution Scheme

In this scheme, let m denote the number of distinct cryptographic keys that can be stored on the key ring of a sensor node. This scheme is divided into three phases as follows.

Phase I: Key Predistribution

In this initialization phase, a random pool (set) of keys Q are picked from the total possible key space. In addition, for each node, m keys are randomly selected from the key pool Q and stored into the node's memory. Each of the m keys has identifiers that will be used to map the keys by the receiving nodes during the discovery phase of this scheme (discussed next). This set of m keys is called the node's key ring. The number of keys in the key pool $|Q|$ (key pool size) is chosen such that any two random subsets of size m in Q will share at least one key, with some probability p.

Phase II: Shared-Key Discovery

On deployment, neighboring sensor nodes begin the discovery process to find out if they share a common key with each other; if they do, then they establish a secure link. There could be many modes for the discovery phase, such as broadcasting the list of identifiers existing in their key ring in clear text or through a challenge-response mechanism. If the probability p were chosen correctly for the network's neighbor density, then the resultant graph of secure links would be connected with some high probability. The remaining links in the graph are then filled in by routing key-establishment messages, along this connected network of initial secure links. From a security perspective, although this approach does not reveal any important information to the adversary, it is still susceptible to a passive traffic analysis attack.

Phase III: Path-Key Establishment

Upon completing the discovery phase, if two nodes in the network discover that they do not share a key between them, they send an encrypted message to neighbors with whom they share a key, with a request to secure connection with the unshared node. This model assumes that after the completion of *Phase II*, there exist many keys in each key ring that can be used for third-party path-key establishment. Hence, the neighboring nodes generate pairwise keys for nodes that do not directly share a key.

Let us now find this probability p that any two nodes with key ring sizes m in the network share at least one common key from the pool Q. Let p' be the probability that two nodes do not share a key between them. Then, p is defined as

$$p = 1 - p' \tag{16.1}$$

In this case, keys from the key ring are drawn from Q without replacement. The total number of possible key rings t_1 is as follows:

$$t_1 = \frac{Q!}{m!(Q-m)!} \tag{16.2}$$

Now, the total number of possible key rings that do not share a key with a particular key ring t_2 is the number of key rings drawn from the remaining Q-m unused keys in the pool:

$$t_2 = \frac{(Q-m)!}{m!(Q-2m)!} \tag{16.3}$$

Then, the probability that no key is shared between any two rings is t_2/t_1. Hence, the probability p is

$$p = 1 - \frac{t_2}{t_1} = 1 - \frac{((Q-m)!)^2}{Q!(Q-2m)!} \tag{16.4}$$

Usually, the value of p is very large in comparison to m, and using the Sterling's approximation for $n!$, the value of p is

$$p = 1 - \frac{\left(1-\dfrac{m}{Q}\right)^{2(Q-m+0.5)}}{\left(1-\dfrac{2m}{Q}\right)^{(Q-2m+0.5)}} \tag{16.5}$$

Figure 16.4 shows the value of p for different values of Q and m. We observe that with the increase in Q, there is a negligible increase in the key ring size m for the same value of p. For example, for $p = 0.5$ and $Q = 6000$, the value of $m = 68$. Subsequently, if the pool size is increased to 10,000, for the same value of $p = 0.5$, m is only increased to 95.

In this scheme, all nodes use the same key pool Q. This implies that the security of the network is gradually eroded as keys from Q are compromised by an adversary that captures more and more nodes. In this scheme, the number of exposed keys is roughly linear to the number of nodes compromised. This characteristic of the basic scheme motivated development of key-predistribution schemes that have better resiliency to node capture. The basic scheme was extended by the q-composite scheme proposed by [24].

q-Composite Scheme

In a q-composite key scheme, instead of designing for a given probability p of sharing a single key, the parameters are altered such that any two nodes have a given probability p of sharing at least q different keys from the key

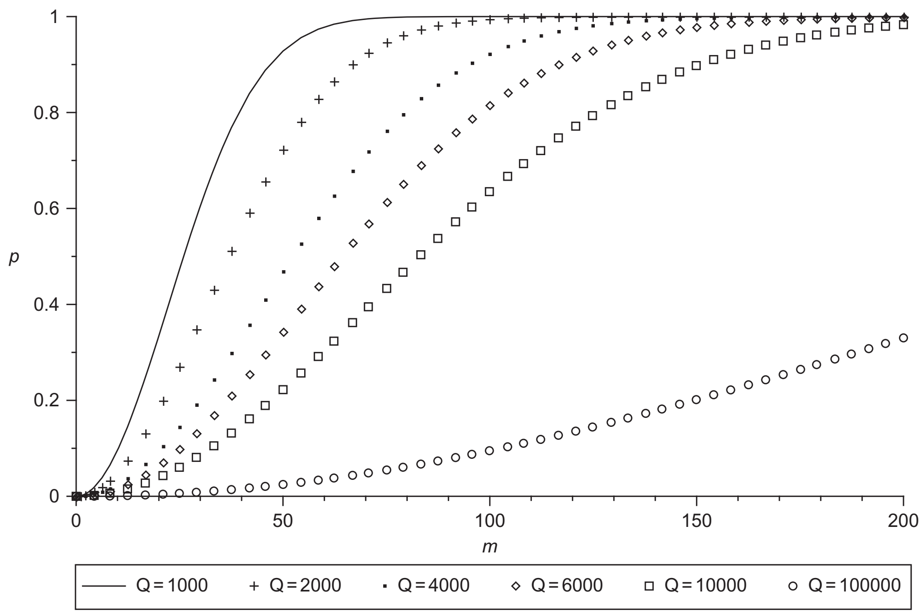

FIGURE 16.4 Probability of sharing at least one shared key using Eschenauer and Gligor's scheme.

pool. All q keys are used in the generation of the key, which encrypts communications between sensor nodes; hence, to eavesdrop on the secured link, the adversary now has to compromise all q keys, instead of just one. As q increases, it is exponentially harder for the attacker to break a link by taking possession of a given set. However, increasing the probability of overlap in this fashion naturally involves reducing the size of the key pool Q. Thus, the smaller key-pool size makes the scheme more vulnerable to an adversary that is capable of compromising larger numbers of sensor nodes.

The key-predistribution phase of this model is similar to *Phase I*, which is discussed later in the chapter, with the only exception being the key-pool size Q. In the shared key-discovery phase, each node must find nodes that share all common keys with each other. The discovery mechanism is similar to that of *Phase II*. Although a broadcast-based approach is susceptible to an eavesdropping attack, alternative methods that are slower but more secure are suggested where the nodes use the Merkle puzzle for key discovery [18]. After the discovery phase, each node would be able to recognize its immediate neighboring nodes with which it would share at least q keys. Subsequently, each node could establish a link between nodes that share at least q keys by hashing the keys in some canonical order. For example, $K = \text{hash}(k_1 \,||\, k_2 \,||\, k_3 \,||\, \ldots \,||\, k_q)$.

In this scheme, the key pool size $|Q|$ plays a critical role because with a larger Q, the probability of any two nodes sharing at least q keys would be much less. Consequently, after bootstrapping, the network may not be connected. On the contrary, if $|Q|$ is small, the security of the network is compromised. Hence, $|Q|$ should be such that the probability of sharing at least q key should be greater than or equal to the probability of successfully achieving a key setup with any of its neighbors. The approach used to calculate the probability of any two nodes sharing exactly i keys $p'(i)$ is similar to calculating p, as shown in Eq. (16.4), and is given as

$$p'(i) = \frac{\binom{|Q|}{i}\binom{|Q|-i}{2(m-i)}\binom{2(m-i)}{m-i}}{\binom{|Q|}{m}^2} \tag{16.6}$$

For example, in Figure 16.5, we find the value of $|Q|$ for a given m and i. In this case, for $m = 200$ and $i = 10$, we achieve a maximum $p'(i)$for $|Q| = 3900$.

In general, random key predistribution presents a desirable trade-off between the insecurity of using a single network-wide key and the impractical high memory overhead of using unique pairwise keys. Its main advantage is that it provides much lower memory overhead than the full pairwise key scheme, while being more resilient to node compromise than the single-network-wide key scheme. Furthermore, it is fully distributed and does not require a trusted base station. The main disadvantages of this approach are the probabilistic nature of the scheme, which makes it difficult to provide the guarantee of the initial graph of secure links being connected under nonuniform conditions or sparse deployments. Furthermore, since keys can be shared between a large number of nodes, this class of schemes does not provide very high resilience against node compromise and subsequent exposure of node keys.

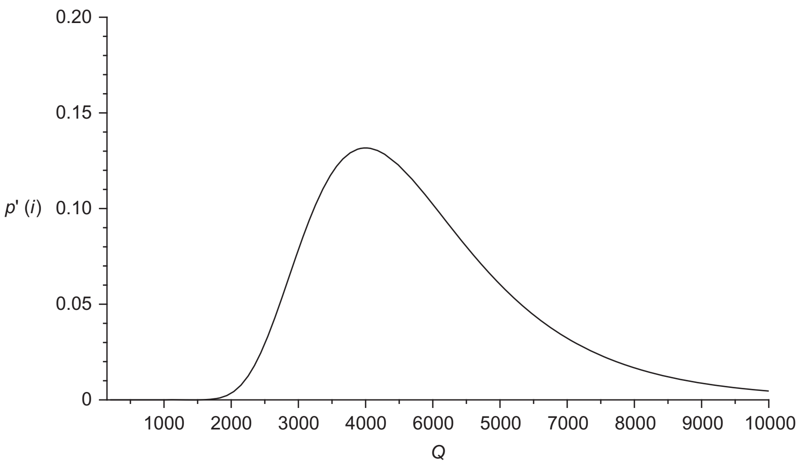

FIGURE 16.5 Key-pool set $|Q|$ selection based on $p'(i)$ for $m = 200$ and $i = 10$.

Random Pairwise Key Scheme

The random pairwise key scheme proposed by [24], is a hybrid of the random key-predistribution scheme and the full pairwise key scheme. In the analysis of random key predistribution, it was deduced that as long as any two nodes can form a secure link with at least a probability p, the entire network will be connected with secure links with high probability. Based on this observation, Chan noted that it is not necessary to perform full pairwise key distribution to achieve a network where any two nodes can find a secure pathway to each other. Instead of preloading $n - 1$ unique pairwise keys in each node, the random pairwise key scheme preloads $m \ll n$ unique pairwise keys from each node. The m keys of a key ring are a small, random subset of the $n - 1$ possible unique keys that this node could share with the other n nodes in the network. By using the same reasoning as the random key-predistribution scheme, as long as these m keys provide sufficient probability p of enabling any two neighboring nodes to establish a secure link, the resultant graph of initial secure links will have a high probability of being connected. The remaining links are then established using this initial graph exactly as in the random key-predistribution scheme.

Chan et al. (2003) present a preliminary initial distributed-node-revocation scheme that makes use of the fact that possessing unique pairwise keys allows nodes to perform node-to-node identity authentication. In their scheme, each of the m nodes that shares a unique pairwise key with the target node (the node's participants) carries a preloaded vote that it can use to signify a message that the target is compromised. These m votes form a Merkle hash tree with m leaves [18]. To vote against the target node, a node performs a network-wide broadcast of its vote (its leaf in the Merkle hash tree) along with the log m internal hash values, which will allow the other participants of the target to verify that this leaf value is part of the Merkle hash tree. Once the t participants of a given target have voted, and the votes have been verified by the other m participants using the Merkle hash tree, all m nodes will erase any pairwise keys shared with the target, thus revoking it from the network.

The random pairwise key scheme inherits both strengths and weaknesses from the full pairwise key scheme and the random key-distribution scheme. Under the random pairwise key scheme, the nodes captured do not reveal information to the rest of the network, and central revocation can be accomplished by just unicasting to each of the nodes that share keys with the revoked node. It also involves a much lower memory overhead than the full pairwise keys scheme. Unfortunately, like the random key-predistribution schemes, it is probabilistic and cannot be guaranteed to work in nonuniform or sparse deployments.

Multispace Key Schemes

This class of schemes is a hybrid between random key predistribution and the λ-secure $n \times n$ key-establishment schemes. (These schemes were first proposed by [25].) Recall that in random key predistribution, a key pool is first selected from the universe of possible keys. Each sensor node is then preloaded with a set of keys from the key pool such that any two nodes possess some chosen probability p of sharing enough keys to form a secure link. Multispace key schemes use the same basic notion of random key predistribution but use key spaces, where individual keys are used in random key predistribution. Hence, the key pool is replaced by a pool of key spaces, and each node randomly selects a subset of key spaces from the pool of key spaces, such that any two nodes will have some common key space with probability p. Each key space represents a unique instance of a different λ-secure $n \times n$ key-establishment scheme [21]. If two nodes possess the same key space, they can then perform

the relevant λ-secure $n \times n$ key-establishment scheme to generate a secure session key.

The main advantage of multispace schemes is that node compromise under these schemes reveals much less information to the adversary than occurs with the random key-predistribution schemes. However, they retain the disadvantage of being probabilistic in nature (no guarantee of success in nonuniform or sparse deployments). Furthermore, they experience the threshold-based sudden security failure mode that is a characteristic of the λ-secure schemes. Other schemes have combined λ-secure schemes with constructions other than random key-space selection. Liu and Ning [26], in particular, describe a deterministic grid-based construction in which key spaces are used to perform intermediary-based key establishment between nodes.

Deterministic Key-Predistribution Schemes

One drawback of the random key-distribution approach is that it does not guarantee success. [27], as well as [28], propose the use of combinatorial design techniques to allocate keys to nodes in such a way as to always ensure key sharing between any two nodes. The amount of memory required per node is typically some fractional power of the overall supported network size ($O(\sqrt{n})$). The main drawback of these schemes is that the same keys are shared between many nodes, leading to weaker resistance to node compromise. [24] have proposed a deterministic scheme using peer nodes as intermediaries in key establishments with similar memory overheads; compared with the combinatorial design approach, this scheme trades off increased communication cost for greater resistance against node compromise.

Public Key Algorithms

Although these algorithms are based on asymmetric key cryptography and are more resource intensive than symmetric key algorithms, they offer better security services, which are much needed and highly advantageous in WSN. As a result, there is motivation to pursue research in developing secure and efficient key-distribution mechanisms suitable in a resource-constraint environment such as WSN. Most of the implementations use Rivest, Shamir, Adleman (RSA) or elliptic curve cryptography (ECC) [12,20].

For example, TinyPK uses the Diffie-Hellman key-exchange technique for key agreement between nodes and is based on the legacy RSA cryptosystem. The main motive of this protocol is to facilitate secure communication between external users and the sensor networks. The external user's identity is established by a CA, where his or her public key is signed by the CA's private key.

Considering the state of the art in large-number factorization, key-size values are usually set to 1024 bits in RSA as lower values are considerably vulnerable to security attacks. In addition, the public key exponent e is set to 3, and all the resource-intensive operations are carried out on external servers. In this model, resource-abundant devices bear the burden of RSA private key operations, and, hence, the sensor nodes maintain higher energy levels during operations.

4. SECURE ROUTING IN WSN

Routing is one of the most fundamental operations in any network that attempts to ensure the delivery of messages from a source to a selected destination. It is a two-step method that involves the process of discovering a suitable route between the concerned source and its destination, and the forwarding of messages using this discovered route. In traditional networks (IP or 3 G networks), routing operations are dedicated to special nodes, such as routers. However, WSNs consist of resource-constraint devices operating in an ad-hoc decentralized manner that requires all the network operations to be done by these ordinary sensor nodes. Some real-time applications (remote-sensing operations) require the routing protocols to facilitate the timely delivery of messages. However, such applications are too resource intensive in WSN and require routing protocols that can balance the energy consumption of the entire network. Furthermore, the number of nodes operating in a WSN scenario is much larger than conventional networks. Consequently, there is a need for the mass production of low-cost nodes. However, with the increase in the number of sensor nodes to meet the current demand for sensor applications, construction of each node to be tamper resistant would be very expensive. As a result, nodes could be susceptible to a node-capture attack. Hence, routing protocols used in traditional networks cannot be applied directly to a resource-constraint environment such as WSN. As a result, new arrays of routing protocols have been designed for WSN [29].

5. ROUTING CLASSIFICATIONS IN WSN

Routing protocols in WSN can be classified by several criteria. Such criteria would be data centricity, location information, network layering and in-network processing, path redundancy, a Quality of Service (QoS) requirement, and network heterogeneity.

Datacentric Communication

Conventional networks such as IP networks use a node-centric routing model in which information is exchanged

using a unique addressing scheme (IP version 4 or 6 or higher). Based on the route the query took to reach the destined node, each source node independently sends data via the shortest path to the concerned sink node. In contrast, a datacentric model is more focused on the aggregated data rather than on identifying the exact node's identifiers. Although the request/response scheme is similar in both of the models, the sink node or cluster head initiates a request for interested data and the responsible nodes respond with the requested data; they vary in the manner in which the nodes send data back to the sink node or cluster heads. The intermediate routing nodes inspect the data that is being sent to the sink node and perform some form of consolidation operation, such that the sink node receives aggregated data from different sources. Figures 16.6 and 16.7 illustrate the distinction between address-centric and datacentric models in WSN. Figure 16.6 shows the address-centric model in which two sources (nodes C and E) send information to the sink node via the shortest path. Node C sends via node A, and node E sends via nodes D and B.

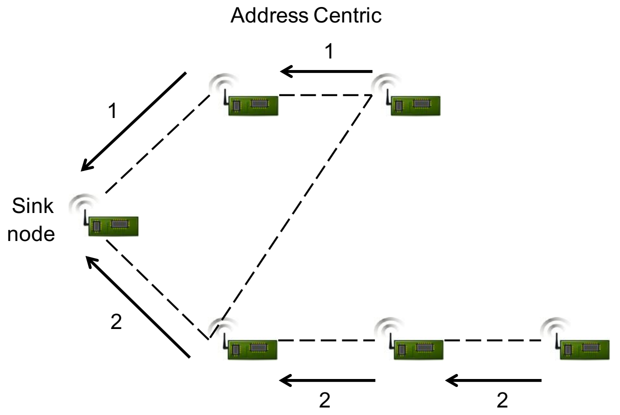

FIGURE 16.6 Address-Centric communication in WSN.

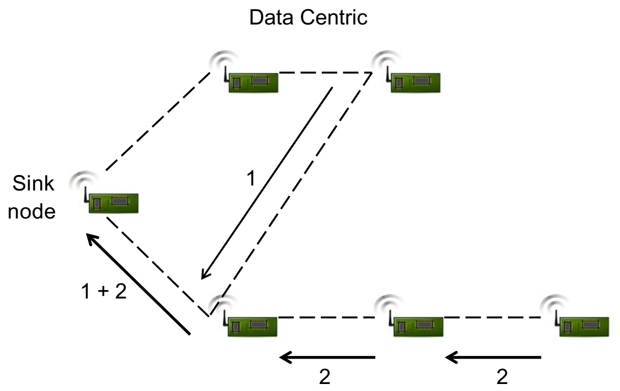

FIGURE 16.7 Datacentric communication in WSN.

In contrast, Figure 16.7 shows the datacentric model in which data from node C is directly sent to node B for consolidation, and, subsequently, the aggregated data is sent to the sink node. In cases where node C cannot directly contact node B, an intermediate node closer to node B is responsible for forwarding the data to node B. On comparing both models, the datacentric model is more energy efficient because only four messages are utilized in sending information from two different sources to the sink node, as opposed to five messages in the address-centric model (Figure 16.6).

Location Information

The physical location of a node in a network is an essential metric for designing routing protocols in a WSN. For example, the protocols could be designed for short- or long-range communication, depending on the position of the nodes. In addition, the positions of the nodes influence the design of the forwarding mechanism, which, in turn, affects the overall energy consumption of the system. In situations in which routing tables or global knowledge of the network is not required, location-based routing could be useful from a scalability point of view. However, one of the major challenges with such networks is that each node should be aware of its position with reference to the sink node. Additionally, the use of Global Positioning System (GPS)-based chips could weigh heavily on the limited resources available in a sensor-network environment, leading to an increase in the price and energy consumption of the system.

Network Layering and In-Network Processing

The architecture of a network could be flat, in the sense that all sensors have the same role. In other words, all sensors forward their sensed data to the sink without necessarily passing through a particular node. A network is said to be *nonlayered* if all sensors form only one group in which the sensors collaborate to accomplish a common monitoring task. On the other hand, the sensors in a network can be grouped into *clusters*, each of which is managed by a specific sensor called a *cluster head*. These types of networks are considered to be *layered*, and, any sensed data should pass through one or more cluster heads before reaching the sink. These cluster heads are supposed to be powerful enough to process the data they receive before sending it to the sink.

All other sensors only need to sense the environment and send their data to the cluster heads for further processing. In some sensing applications, redundancy and correlation exist in the gathered data. Hence, it would be desirable to only transmit more representative data. For

example, in monitoring the temperature of a room, the variation in the data within a given region is expected to be small. Thus, the sink is not interested in receiving all the temperature measures, but rather only some of them. This can significantly reduce the communication overhead introduced by data forwarding and improve network performance. In addition, the concept of layering makes a network more scalable and leads to more efficient usage of the energy of sensors, thus extending the network's lifetime.

Extending the network's lifetime is an ultimate goal in the design of a WSN. Given that most of the energy of a sensor is mainly consumed in processing, sensing, and communication, an efficient design approach should take into account these three components of energy consumption. A question that network designers are mostly concerned about is, *How can the lifetime of a network be extended?* To address this problem, several energy-efficient routing and data-dissemination protocols have been proposed that focus on how to forward the data until they reach the sink, regardless of the type of data being transmitted from the source sensors to the sink. Among those protocols, one class does not update the data at the intermediate sensors. That is, each intermediate sensor only acts as a pure data relay without altering any of the data it has received. Another class of protocols introduces the concept of *in-network processing* to handle unnecessary redundancy and correlation contained in the sensed data.

In many applications, the data sensed by the sensors has a certain amount of redundancy and correlation. It would be desirable if the sink could only receive relevant data, for faster and better decision making. For this purpose, the sensed data should be processed at intermediate sensors before reaching the sink. The benefit of this in-network processing, such as data fusion, can be seen when vector data rather than scalar data are being transmitted. For example, in an application monitoring the temperature of a room, the sensed data is scalar (integer or real values). Hence, the cost of data communication is not very high, and the data fusion or aggregation is not as costly. But continuously sending unnecessary and redundant data will consume a huge amount of energy. If a sensing application has to send a large amount of data, for example, images, to the sink for further analysis and processing, it would consume a huge amount of energy. In this case, it would be more beneficial if those images, sensed by different sensors, could be aggregated and only a few of them sent. However, it is also true that processing those images for data fusion requires a considerable amount of energy. Moreover, there will be a delay due to the processing of those images. Therefore, there is a trade-off between data communication and fusion, in these types of information-intensive networks, where the sensed data is not scalar but rather vector.

Path Redundancy

The design of WSN not only should consider scalability and energy efficiency but should also be robust in nature, which means that a network remains operational despite the occurrence of sensor-node and link failures. The reasons for the failure could be intentional (security attack) or unintentional (defective node or natural calamity). One of the approaches to make the system more robust is to incorporate multipath routing. In short, multipath routing implies the existence of multiple paths (disjoint or partially disjoint) between source node and destination sensors (cluster heads or sink node) [30].

Although maintaining alternate paths in a routing table introduces some overhead and consumes more energy, multipath routing is an effective technique to improve robustness when link failures occur. Link failures could occur for many different reasons, such as frequent topological changes due to unreliable wireless communication links. Moreover, multipath routing enables recovery from sensor and link failures and provides the necessary resilience to the network at the cost of excessive redundancy.

Quality of Service (QoS)

WSN applications have varied requirements that are usually expressed in terms of some metrics, such as delay, fault tolerance, and reliability. For example, real-time applications (video surveillance) are dependent on delay bounds.

Hence, for such applications, the sensed data must reach the sink within a certain time. In addition, a desired property of WSN applications is fault tolerance, which means that a network should remain functional in the event of sensor or link failures. Another desired property is reliability, wherein the aggregated data should be received by the sink, as correctly as possible. This would ensure accurate decision making by the sink node. However, metrics such as fault tolerance and reliability necessitate the deployment of additional sensors, yielding additional energy consumption, so that the network can recover swiftly and deliver accurate sensed data to the sink, despite some sensor or link failures. Hence, routing and data-dissemination protocols should consider the trade-offs between fault tolerance, reliability, energy, and delay. Recall that energy is a constraint that should be considered by any routing and data-dissemination protocol to guarantee efficient usage of the amount of energy available at each sensor.

Network Dynamics

Requirements such as limited-energy use (discussed previously) and goals such as mobility have had direct impact on the design decisions of WSN network topology. In theory, a deterministic sensor deployment approach would provide even coverage of the area that has to be sensed. In addition, this approach would require fewer sensor nodes for accomplishing the required sensing task. However, in a real environment with an uneven terrain, it can be extremely challenging to apply a deterministic sensor deployment strategy. As a result, we are only left with the option of distributing the nodes in a random fashion. Consequently, not all areas of the sensing region are evenly covered by the sensors, thus leading to a coverage hole. In addition, there is a possibility of not all sensor nodes in the network being connected with each other or even with the sink node. In such situations, mobility plays an important role and becomes the main source of network dynamics that can be used to solve problems. In any sensor network, the aggregated data will be transmitted over some established paths between the source sensors and the cluster heads or sink node. And the establishment of optimal paths depends on whether the sensors are static or mobile. Hence, routing and data-dissemination protocols can be classified based on whether a network is static or dynamic.

In a static network, every node in the network is static—that is, both the sensors and the sink node remain in their fixed positions during their collaborative operation of monitoring a physical environment. Therefore, there is not much overhead required to maintain routes between the sensors and the sink and between the sensors themselves. In particular, the positions of the sensors and the sink can be learned before data exchange by exchanging some control messages. In certain cases, if the terrain is familiar, node positions can be preconfigured in nodes before deployment. Furthermore, neighbors of a given sensor do not change unless a new sensor has joined the network or an existing sensor has left the network, either by its own will or because of exhaustion of its battery life.

In a mobile network, either the sensors or the sinks or cluster heads are moving. As a result, the routes between the sensors and the sink are changing frequently in such a dynamic environment. Hence, a currently active route could at any time become inactive. This route instability would result in additional overhead and delay in discovering valid routes for data transmission and forwarding. To overcome this drawback, routing algorithms have been proposed in which the ordinary sensors and sinks are designed to be static, whereas certain relay nodes such as cluster heads could be mobile. One such example is the mobile ubiquitous LAN extensions (MULES)-based architecture [31].

In conclusion, the need for mobility in WSN is application dependent. For example, in applications that measure temperature, humidity, sound, or light in an enclosed area, there is no need to have mobile sensors or a mobile sink. However, in monitoring a moving object in a battlefield environment, or in monitoring endangered species, there is a need for mobile sensors in the network to efficiently track the object. In such scenarios, it has been observed that the use of mobile relays helps increase the lifetime of a WSN.

Network Heterogeneity

Early research on sensor networks focused on homogeneous network architecture. However, recently heterogeneous sensor networks have experienced increasing popularity because they significantly increase the lifetime and reliability of the system. A heterogeneous sensor network usually consists of a large number of low-cost nodes for the sensing operation and a few resource-abundant nodes that primarily perform data filtering, aggregation, and transport operations. Although heterogeneous networks have gained precedence over homogeneous networks, the efficient realization of heterogeneity in a sensor network requires prior systematic planning for placing these heterogeneous resources in a resource-aware manner [32].

Routing Protocols in WSN

Routing in ad-hoc networks has been very challenging owing to node mobility. Hence, a routing path established in the beginning between the source and the destination may not exist at a later time interval. Furthermore, in a resource-constraint environment such as WSN, the energy levels of the intermediate nodes must be considered in making routing decisions.

Routing protocols in WSN can be broadly classified into proactive, reactive, hybrid, and location-aware routing protocols [33]. In a proactive routing scheme, each node maintains an up-to-date routing table by frequently querying its immediate neighbors for routing information. An example of such a scheme is the Destination Sequenced Distance Vector (DSDV) routing protocol [34]. However, one of the major drawbacks of such schemes is the additional overhead due to frequent routing updates. In contrast, reactive routing involves on-the-fly route establishment and is demand driven. It is based on a request−response model. The initial discovery phase, to find the destined node, could involve flooding, and the response phase establishes the transient active routing path. Examples include Ad-hoc On-Demand Distance Vector (AODV) routing and Dynamic Source Routing (DSR) [35,36].

Various hybrid protocols use the node-discovery method of the proactive routing protocol, along with the on-the-fly routing-path establishment method to produce a hybrid version of the protocol. The Zone Routing Protocol (ZRP) is an example of such a hybrid scheme [37]. In position-aware routing protocols, the nodes select the geographically closest neighboring node when making routing decisions. An example of such a protocol is the Geographic- and Energy-Aware Routing (GEAR) protocol [38]. However, GEAR does not take security into consideration. Most of the security schemes in WSN have focused on symmetric-key cryptography, due to the notion that asymmetric-key cryptography (RSA-based algorithms) was computationally intensive. However, symmetric-key cryptography has major drawbacks with regard to key management, and the security is based on preshared secret keys. With the successful implementation of pairing-based cryptographic algorithms in WSN, a new platform is provided to implement asymmetric-key cryptographic schemes in WSN [20].

Selective-Forwarding Attack in WSN

Many routing protocols in WSN use a breadth-first spanning-tree algorithm to broadcast routing updates [5,39]. The sink node periodically broadcasts updated routing information to its immediate cluster heads. Then, these cluster heads re-broadcast this information to their immediate neighbors, and the process continues recursively. During this process, each intermediate node makes a note of its parent node, where the parent node is the first node that was able to make contact with its subordinate node and relay the routing information. When all the active nodes are operational, they should send all the sensed data to their parent node. However, this protocol is vulnerable to many attacks.

Cross-Layer Design Approach in WSN

Recently, a flurry of cross-layer design schemes have been proposed in WSN. As the fusion of secure networking and wireless communication occupies center stage in sensor networks, the traditional layered protocol architecture on which most of the networks form their basis has come under scrutiny. Although the layered approach has been repeatedly used in wired networks, it has been argued that the same approach cannot be directly applied in resource-constraint, wireless ad-hoc networks such as WSN. To combat this approach, security researchers have proposed several cross-layer design schemes in an ad-hoc environment [40]. Unlike the layering approach, where protocols at each layer are designed independently, cross-layer designs aim at exploiting the dependence between different protocol layers to achieve maximum performance gains. In the current state of the art in the paradigm of cross-layer design schemes in ad-hoc wireless networks, several diverse interpretations exist. One of the main reasons for such varied explanations is that the design effort is largely dominated by researchers who have made independent efforts in designing different layers of the stack. Many of the cross-layer designs depend on other cross-layer designs and hence raise the fundamental question of the coexistence of different cross-layer design proposals. In addition, the question of time synchronization between various cross-layer schemes and the roles each layer of the stack plays is an active area of research. The wireless medium allows richer modalities of communication than wired networks. For example, nodes can make use of the inherent broadcast nature of the wireless medium and cooperate with each other.

Employing modalities such as node cooperation in protocol design also calls for cross-layer design. The goal of designing security solutions with a cross-layer design approach takes us to a new paradigm of security research. The main objective of security solutions in a network is to provide security services such as authentication, integrity, confidentiality, and availability to the users. In wireless ad-hoc networks, due to the unreliable nature of the shared radio medium, attackers can launch varying attacks, ranging from passive reconnaissance attacks to active man-in-the-middle attacks. Routing in WSN is hop by hop and assumes a trusted, cooperative environment as intermediate nodes act as relays. However, compromised intermediate nodes can launch varying routing attacks, such as black-hole, wormhole, flood rushing, and selective-forwarding attacks. In this part of the chapter, we review the existing state of the art in the cross-layer design from a security perspective. In addition, as an example, we look at a cross-layer key-distribution mechanism.

In recent times, several cross-layer design schemes have been proposed. Cross-layer feedback optimization could be implemented on the sink or the sensor nodes. The cross-layer interactions among the layers can be categorized in different ways. For example, lower to upper (violation in the flow control from bottom to top), upper to lower (violation in the flow control from top to bottom), and lower and upper. In all these cases, new interfaces will be created between layers. In addition, cross-layer designs can be categorized by the integration of adjacent layers, design coupling without interfaces, and horizontal calibrations.

Lower to Upper

The requirement of information from the lower layer to the upper layer at runtime results in the creation of a new

interface between these two layers. In this case, the lower layers update necessary information to the appropriate upper layers via the interface. For example, the data link layer is made aware of the transmit power, and the bit error rate information by the physical layer so that it can adjust its error-correction mechanism. Subsequently, the transport layer can inform the application layer about the TCP packet loss, as it would help the upper layer in the stack (application layer) to adjust its transmitting rate. In addition, it should be noted that self-adaptation loops should not be part of a cross-layer design approach, as they do not require new interfaces to be created between the necessary lower and upper layers. For example, in an auto-rate fallback mechanism for rate selection in a wireless networking environment with multirate physical layers, the Medium Authentication Code (MAC) layer rate selection is dependent on the received acknowledgment that is observable at the MAC layer. Hence, this mechanism would not qualify as a cross-layer design approach as there is no need to create new interfaces for rate adoption.

Upper to Lower

The upper layers provide updated information to the necessary lower layers via an interface. For example, if the application layer senses a delay or loss of data, a direct notification to the data link layer by the application layer would help adapt its error correction mechanism. In addition, delay sensitive packets could be treated with priority. As proposed by Larzon, Bodin, and Schelen [41], lower-to-upper information flow is treated as notifications (the lower layer notifies the upper layer about the underlying network condition), whereas the upper-to-lower information flow is treated as hints (upper layers provide hints to the lower layers on the means to process application data).

Lower and Upper

In this case, both the upper and lower layers are at liberty to transmit notifications about their current state and send queries to the other layers. During runtime, layers executing different tasks can collaborate with each other on an iterative loop basis, resulting in a back and forth communication between them. For example, a back and forth information flow between layers is seen in a proposal to solve the multiple access problem for contention-based wireless ad-hoc networks using joint scheduling and suggesting a distributed power-control algorithm for such networks [42]. In addition, direct communication between layers at runtime could indicate the advantage of making the variables at each layer visible to the other layers of the stack. However, one disadvantage of this approach would be in managing the shared memory spaces between the layers when variables and internal states are shared between different layers.

Integration of Adjacent Layers

The formation of a super-layer by combining two or more adjacent layers would result in a new cross-layer design scheme. The resulting layer would simply provide the union of the services that were provided by the individual layers. For example, a collaborative design of the data-link and physical layer would suffice to produce a super-layer. From a network security perspective, a super-layer that combines network and data link layer would help prevent advanced Address Resolution Protocol (ARP) poisoning attacks.

Design Coupling without Interfaces

Coupling two or more layers during the design phase would avoid creating extra interfaces at runtime that could result in a new cross-layer design approach. However, in deployed networks, one of the architectural challenges would be to integrate the coupled layer with already-existing fixed layers.

Vertical and Horizontal Calibration across Layers

Vertical calibration: Vertical calibration refers to the efficient utilization of parameters across different layers of the vertical stack. The parameters set at the application level could dictate terms to the lower layers and vice versa. For example, the transport protocol (TCP or UDP) chosen at the transport layer would assert reliable or unreliable communication and would directly affect the layers below it. Consequently, the joint adjustment at different layers of the vertical stack would result in a more holistic performance of the system than the adjustment of individual parameters.

Horizontal Calibration

Horizontal calibration could be very useful in a resource-constraint environment such WSN. In this case, not only individual parameters pertaining to that layer are taken into consideration, but parameters pertaining to other compatriot layers are also considered. For example, while routing packets, if the network level state of intermediate nodes is taken into consideration, it would be easy to detect nonactive nodes and could subsequently result in an energy-efficient routing protocol. However, challenges do exist in case the participating nodes do not adhere to the same cross-layer approach as the initiating node.

6. WSN SECURITY FRAMEWORK AND STANDARDS

The standardization of wireless sensor networks proceeds along two main directives: the IEEE 802.15.4 standard [43] and ZigBee [11]. The IEEE 802.15.4 standard defines the physical and Medium access control (MAC) layers, and ZigBee defines the network and application layers. In WSN implementations, the two protocol stacks can be combined to provide low data rate and long-lasting applications on battery-powered wireless devices.

IEEE 802.15.4

The IEEE 802.15.4 MAC layer provides marginal support for security, and the advanced security features (key management and authentication) are the responsibility of the upper layers in the WSN protocol stack. In addition, the MAC layer security services assume that the keys are generated, transmitted, and stored by the upper layers in a secure manner.

The security services provided by the MAC layer include access control, data encryption, frame integrity, and sequential freshness. It should be noted that the security features of the MAC layer are optional and that the use of this feature is at the discretion of the applications existing on the application layer.

ZigBee

The ZigBee Alliance is an association of companies working together to develop standards (and products) for reliable, cost-effective, low-power wireless networking [2]. ZigBee is an emerging technology and is being used in a wide range of products and applications across consumer, commercial, industrial, and government markets worldwide. It builds upon the IEEE 802.15.4 standard described previously. The ZigBee specifications provide authentication, data freshness, message integrity, and encryption:

- *Authentication:* Network-level authentication is achieved by using a common network key. This prevents outsider attacks while adding very little in memory cost. Device level authentication is achieved by using unique link keys between pairs of devices. This prevents insider and outsider attacks but has higher memory cost.
- *Freshness:* ZigBee devices use incoming and outgoing freshness counters to maintain data freshness. These counters are reset every time a new key is created. Devices that communicate once per second will not overflow their freshness counters for 136 years.
- *Message Integrity*: ZigBee specifications provide the options of providing 0-, 32-, 64- or 128-bit data integrity for the transmitted messages. The default is 64-bit integrity.
- *Encryption:* ZigBee uses 128-bit Advanced Encryption Standard (AES) encryption. Encryption protection is possible at the network or device level. Network-level encryption is achieved by using a common network key. Device-level encryption is achieved by using unique link keys between pairs of devices. Encryption can be turned off without impacting freshness, integrity, or authentication, as some applications may not need any encryption.

The closest competitor to ZigBee in personal area network technology is Bluetooth. Although Bluetooth claims a much faster data rate (1 Mbps vs. 250 kbps), ZigBee specifies a longer transmission range and is specifically designed for low-power consumption. If Bluetooth is used in modular robotics applications, it requires a central coordinator and is limited to small networks. However, ZigBee does not have this limitation.

7. SUMMARY

Organizations and individuals benefit when wireless sensor networks and devices are protected. After assessing the risks associated with wireless sensor network technologies, organizations can reduce the risks by applying countermeasures to address specific threats and vulnerabilities. These countermeasures include management, operational, and technical controls. While these countermeasures will not prevent all penetrations and adverse events, they can be effective in reducing many of the common risks associated with wireless sensor networks technology.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Although WSNs have gained a little popularity, there are some serious limitations when implementing security.
2. True or False? WSNs operate in a resource-constrained environment and therefore deviate from the traditional Open System Interconnection (OSI) model.
3. True or False? In WSN, threats to privacy can be further classified into reconnaissance.

4. True or False? The man-in-the-middle attack is not one of the classical attacks that can be executed in a WSN environment.
5. True or False? Due to threats to the WSN, some portion of the network or some of the functionalities or services provided by the network could be damaged and available to the participants of the network.

Multiple Choice

1. The middle layer provides one of the following for applications existing in the upper layers:
   A. RC 4 stream cipher
   B. Temporal Key Integrity Protocol (TKIP)
   C. Application programming interface
   D. Message Integrity Code (MIC)
   E. Extensible Authentication Protocol (EAP) framework
2. Which of the following is responsible for flow and congestion control?
   A. Middle layer
   B. Network layer
   C. Transport layer
   D. Data link layer
   E. All of the above
3. What allows organizations to reason about attacks at a level higher than a simple list of vulnerabilities?
   A. Secure on-demand routing protocol
   B. Taxonomy
   C. Message Authentication Code (MAC)
   D. Authenticated Routing for Ad hoc Networks (ARAN)
   E. Destination-Sequenced Distance Vector (DSDV) routing
4. In what type of attack is the attacker able to intercept and monitor data between communicating nodes, but does not tamper or modify packets for fear of raising suspicion of malicious activity among the nodes?
   A. Active attack
   B. Privacy attack
   C. Eavesdropping attack
   D. Man-in-the-middle attack
   E. Passive attack
5. What occurs when an attacker floods the victim with bogus or spoofed packets with the intent of lowering the response rate of the victim?
   A. HELLO flood attack
   B. Denial-of-service attack
   C. Sinkhole attack
   D. Sybil attack
   E. All of the above

1. INTRODUCTION

Cellular networks are high-speed, high-capacity voice and data communication networks with enhanced multimedia and seamless roaming capabilities for supporting cellular devices. With the increase in popularity of cellular devices, these networks are used for more than just entertainment and phone calls. They have become the primary means of communication for finance-sensitive business transactions, lifesaving emergencies, and life-/ mission-critical services such as E-911. Today these networks have become the lifeline of communications.

A breakdown in a cellular network has many adverse effects, ranging from huge economic losses due to financial transaction disruptions; loss of life due to loss of phone calls made to emergency workers; and communication outages during emergencies such as the September 11, 2001, attacks. Therefore, it is a high priority for cellular networks to function accurately.

It must be noted that it is not difficult for unscrupulous elements to break into a cellular network and cause outages. The major reason for this is that cellular networks were not designed with security in mind. They evolved from the old-fashioned telephone networks that were built for performance. To this day, cellular networks have numerous well-known and unsecured vulnerabilities providing access to adversaries. Another feature of cellular networks is network relationships (also called *dependencies*) that cause certain types of errors to propagate to other network locations as a result of regular network activity. Such propagation can be very disruptive to a network, and in turn it can affect subscribers. Finally, Internet connectivity to cellular networks is another major contributor to cellular networks' vulnerability because it gives Internet users direct access to cellular network vulnerabilities from their homes.

To ensure that adversaries do not access cellular networks and cause breakdowns, a high level of security must be maintained in cellular networks. However, though great efforts have been made to improve cellular networks in terms of support for new and innovative services, greater number of subscribers, higher speed, and larger bandwidth, very little has been done to update the security of cellular networks. Accordingly, these networks have become highly attractive targets to adversaries, not only because of their lack of security but also due to the ease with which these networks can be exploited to affect millions of subscribers.

In this chapter we analyze the security of cellular networks. Toward understanding the security issues in cellular networks, the rest of the chapter is organized as follows. We present a comprehensive overview of cellular networks with a goal of providing a fundamental understanding of their functioning. Next we present the current state of cellular network security through an in-depth discussion on cellular network vulnerabilities and possible attacks. In addition, we present a cellular network specific attack taxonomy. Finally, we present a review of current cellular network vulnerability assessment techniques and conclude with a discussion.

2. OVERVIEW OF CELLULAR NETWORKS

The current cellular network is an evolution of the early-generation cellular networks that were built for optimal performance. These early-generation cellular networks were proprietary and owned by reputable organizations. They were considered secure due to their proprietary ownership and their *closed nature*, that is, their control infrastructure was unconnected to any public network (such as the Internet) to which end subscribers had direct

access. Security was a nonissue in the design of these networks.

Recently, connecting the Internet to cellular networks has not only imported the Internet vulnerabilities to cellular networks, it has also given end subscribers direct access to the control infrastructure of a cellular network, thereby opening the network. Also, with the increasing demand for these networks, a large number of new network operators have come into the picture. Thus, the current cellular environment is no longer a safe, closed network but rather an insecure, open network with many unknown network operators having nonproprietary access to it. Here we present a brief overview of the cellular network architecture.

Overall Cellular Network Architecture

Subscribers gain access to a cellular network via radio signals enabled by a radio access network, as shown in Figure 17.1. The radio access network is connected to the wireline portion of the network, also called the *core network*. Core network functions include servicing subscriber requests and routing traffic. The core network is also connected to the Public Switched Telephone Network (PSTN) and the Internet, as illustrated in Figure 17.1[1].

The PSTN is the circuit-switched public voice telephone network that is used to deliver voice telephone calls on the *fixed landline telephone network*. The PSTN uses Signaling System No. 7 (SS7), a set of telephony signaling protocols defined by the International Telecommunication Union (ITU) for performing telephony functions such as call delivery, call routing, and billing. The SS7 protocols provide a universal structure for telephony network signaling, messaging, interfacing, and network maintenance. PSTN connectivity to the core network enables mobile subscribers to call fixed network subscribers, and vice versa. In the past, PSTN networks were also closed networks because they were unconnected to other public networks.

The core network is also connected to the Internet. Internet connectivity allows the cellular network to provide innovative multimedia services such as weather reports, stock reports, sports information, chat, and electronic mail. Interworking with the Internet is possible using protocol gateways, federated databases, and multiprotocol mobility managers [2]. Interworking with the Internet has created a new generation of services called *cross-network services*. These are multivendor, multidomain services that use a combination of Internet-based data and data from the cellular network to provide a variety of services to the cellular subscriber. A sample cross-network service is the *Email Based Call Forwarding Service* (CFS), which uses Internet-based email data (in a mail server) to decide on the call-forward number (in a call-forward server) and delivers the call via the cellular network.

From a functional viewpoint, the core network may also be further divided into the circuit-switched (CS) domain, the packet-switched (PS) domain, and the IP Multimedia Subsystem (IMS). In the following, we further discuss the core network organization.

Core Network Organization

Cellular networks are organized as collections of interconnected *network areas*, where each network area covers a fixed geographical region (as shown in Figure 17.2). At a particular time, every subscriber is affiliated with two networks: the *home network* and the *visiting network*.

Every subscriber is permanently assigned to the home network (of his device), from which they can roam onto other visiting networks. The home network maintains the subscriber profile and his current location. The visiting network is the network where the subscriber is currently roaming. It provides radio resources, mobility management, routing, and services for roaming subscribers. The visiting network provides service capabilities to the subscribers on behalf of the home environment [3].

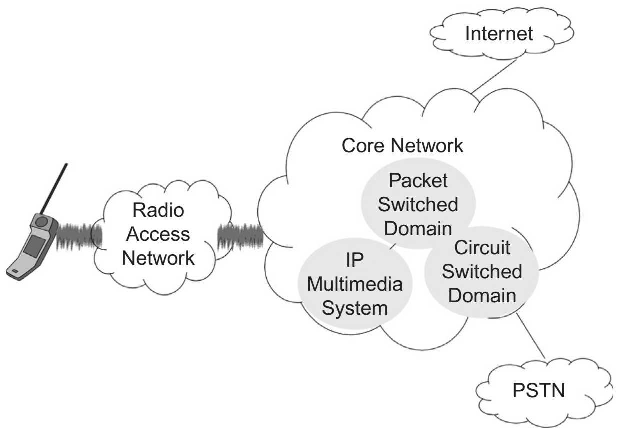

FIGURE 17.1 Cellular network architecture.

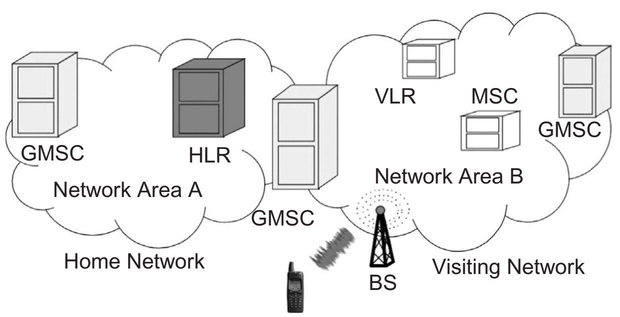

FIGURE 17.2 Core network organization.

The core network is facilitated by network servers (also called *service nodes*). Service nodes are composed of (1) a variety of *data sources* (such as cached read-only, updateable, and shared data sources) to store data such as subscriber profile and (2) *service logic* to perform functions such as computing data items, retrieving data items from data sources, and so on.

Service nodes can be of different types, with each type assigned specific functions. The major service node types in the circuit-switched domain include the Home Location Register (HLR), the Visitor Location Register (VLR), the Mobile Switching Center (MSC), and the Gateway Mobile Switching Center (GMSC) [4].

All subscribers are permanently assigned to a fixed HLR located in the home network. The HLR stores permanent subscriber profile data and relevant temporary data such as current subscriber location (pointer to VLR) of all subscribers assigned to it. Each network area is assigned a VLR. The VLR stores temporary data of subscribers currently roaming in its assigned area; this subscriber data is received from the HLR of the subscriber. Every VLR is always associated with an MSC. The MSC acts as an interface between the radio access network and the core network. It also handles circuit-switched services for subscribers currently roaming in its area. The GMSC is in charge of routing the call to the actual location of the mobile station. Specifically, the GMSC acts as interface between the fixed PSTN network and the cellular network. The radio access network comprises a transmitter, receiver, and speech transcoder called the base station (BS) [5].

Service nodes are geographically distributed and serve the subscriber through collaborative functioning of various network components. Such collaborative functioning is possible due to the inter-component network relationships (called dependencies). A *dependency* means that a network component must rely on other network components to perform a function. For example, there is a *dependency* between service nodes to service subscribers. Such a dependency is made possible through signaling messages containing data items. Service nodes typically request other service nodes to perform specific operations by sending them signaling messages containing data items with predetermined values. On receiving signaling messages, service nodes realize the operations to perform based on values of data items received in signaling messages. Further, dependencies may exist between data items so that received data items may be used to derive other data items. Several application layer protocols are used for signaling messages. Examples of signaling message protocols include Mobile Application Part (MAP), ISDN User Part (ISUP), and Transaction Capabilities Application Part (TCAP) protocols.

Typically in a cellular network, to provide a specific service a preset group of signaling messages is exchanged between a preset group of service node types. The preset group of signaling messages indicates the operations to be performed at the various service nodes and is called a *signal flow*. In the following, we use the *call delivery service* [6] to illustrate a signal flow and show how the various geographically distributed service nodes function together.

Call Delivery Service

The *call delivery service* is a basic service in the circuit-switched domain. It is used to deliver incoming calls to any subscriber with a mobile device regardless of their location. The signal flow of the call delivery service is illustrated in Figure 17.3. The call delivery service signal

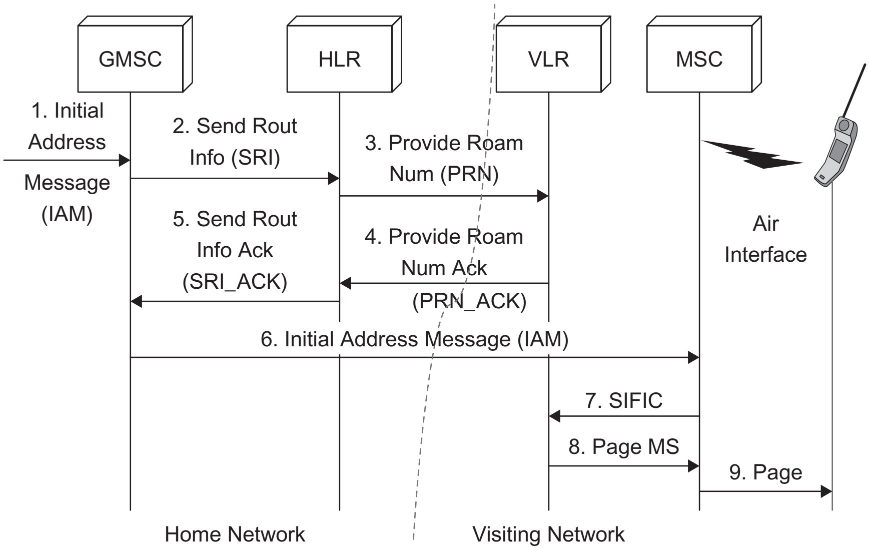

FIGURE 17.3 Signal flow in the call delivery service.

flow comprises MAP messages SRI, SRI_ACK, PRN, and PRN_ACK; ISUP message IAM; and TCAP messages SIFIC, Page MS, and Page.

Figure 17.3 illustrates the exchange of signal messages between different network areas. It shows that when a subscriber makes a call using his mobile device, the call is sent in the form of a signaling message IAM to the nearest GMSC, which is in charge of routing calls and passing voice traffic between different networks. This signaling message IAM contains data items such as *called number* that denotes the mobile phone number of the subscriber receiving this call. The *called number* is used by the GMSC to locate the address of the HLR (home network) of the called party. The GMSC uses this address to send the signaling message SRI.

The SRI message is an intimation to the HLR of the arrival of an incoming call to a subscriber with *called number* as mobile phone number. It contains data items such as the *called number* and *alerting pattern*. The *alerting pattern* denotes the pattern (*packet-switched data, short message service*, or *circuit-switched call*) used to alert the subscriber receiving the call. The HLR uses the *called number* to retrieve from its database the current location (pointer to VLR) of the subscriber receiving the call. The HLR uses this subscriber location to send the VLR the message PRN. The PRN message is a request for call routing information (also called *roaming number*) from the VLR where the subscriber is currently roaming. The PRN message contains the *called number*, *alerting pattern*, and other *subscriber call profile* data items.

The VLR uses the *called number* to store the *alerting pattern* and *subscriber call profile* data items and assign the *roaming number* for routing the call. This *roaming number* data item is passed on to the HLR (in message PRN_ACK), which forwards it to the GMSC (in message SRI_ACK). The GMSC uses this *roaming number* to route the call (message IAM) to the MSC where the subscriber is currently roaming. On receipt of the message IAM, the MSC assigns the *called number* resources for the call and also requests the *subscriber call profile* data items, and *alerting pattern* for the *called number* (using message SIFIC) from the VLR, and receives the same in the Page MS message. The MSC uses the *alerting pattern* in the incoming call profile to *derive* the *page type* data item. The *page type* data item denotes the manner in which to alert the mobile station. It is used to page the mobile subscriber (using message Page). Thus subscribers receive incoming calls irrespective of their locations.

If data item values are inaccurate, a network can misoperate and subscribers will be affected. Hence, accurate functioning of the network is greatly dependent on the integrity of data item values. Thus signal flows allow the various service nodes to function together, ensuring that the network services its subscribers effectively.

3. THE STATE OF THE ART OF CELLULAR NETWORK SECURITY

This part of the chapter presents the current state of the art of cellular network security. Because the security of a cellular network is the security of each aspect of the network, that is, radio access network, core network, Internet connection, and PSTN connection, we detail the security of each in detail.

Security in the Radio Access Network

In a cellular network, the radio access network uses radio signals to connect the subscriber's cellular device with the core network. Hence it would seem that attacks on the radio access network could easily happen because anyone with a transmitter/receiver could capture these signals. This was very true in the case of early-generation cellular networks (first and second generations), where there were no guards against eavesdropping on conversations between the cellular device and BS; cloning of cellular devices to utilize the network resources without paying; and cloning BSs to entice users to camp at the cloned BS in an attack is called a *false base station attack*, so that the target user provides secret information to the adversary.

In the current generation (third-generation) of cellular networks, all these attacks can be prevented because the networks provide adequate security measures. Eavesdropping on signals between the cellular device and BS is not possible, because cipher keys are used to encrypt these signals. Likewise, replay attacks on radio signals are voided by the use of non-repeating random values. Use of integrity keys on radio conversations voids the possibility of deletion and modification of conversations between cellular devices and BSs. By allowing the subscriber to authenticate a network, and vice versa, this generation voids the attacks due to cloned cellular devices and BSs. Finally, as the subscriber's identity is kept confidential by only using a temporary subscriber identifier on the radio network, it is also possible to maintain subscriber location privacy [7].

However, the current generation still cannot prevent a denial-of-service attack from occurring if a large number of registration requests are sent via the radio access network (BS) to the visiting network (MSC). Such a DoS attack is possible because the MSC cannot realize that the registration requests are fake until it attempts to authenticate each request and the request fails. To authenticate each registration request, the MSC must fetch the authentication challenge material from the corresponding HLR. Because the MSC is busy fetching the authentication challenge material, it is kept busy and the genuine registration requests are lost [7]. Overall there is a great

improvement in the radio network security in the current third-generation cellular network.

Security in Core Network

Though the current generation of a cellular network has seen many security improvements in the radio access network, the security of the core network is not as improved. Core network security is the security at the service nodes and security on links (or wireline signaling message) between service nodes.

With respect to wireline signaling message security, of the many wireline signaling message protocols, protection is only provided for the Mobile Application Part (MAP) protocol. The MAP protocol is the cleartext application layer protocol that typically runs on the security-free SS7 protocol or the IP protocol. MAP is an essential protocol and it is primarily used for message exchange involving subscriber location management, authentication, and call handling. The reason that protection is provided for only the MAP protocol is that it carries authentication material and other subscriber-specific confidential data; therefore, its security was considered top priority and was standardized [8−10]. Though protection for other signaling message protocols was also considered important, it was left as an improvement for the next-generation networks [11].

Security for the MAP protocol is provided in the form of the newly proposed protocol called Mobile Application Part Security (MAPSec), when MAP runs on the SS7 protocol stack, or Internet Protocol Security (IPSec) when MAP runs on the IP protocol. Both MAPSec and IPSec, protect MAP messages on the link between service nodes by negotiating security associations. Security associations comprise keys, algorithms, protection profiles, and key lifetimes used to protect the MAP message. Both MAPSec and IPSec protect MAP messages by providing source service node authentication and message encryption to prevent eavesdropping, MAP corruption, and fabrication attacks.

It must be noted that though MAPSec and IPSec are deployed to protect individual MAP messages on the link between service nodes, signaling messages typically occur as a group in a signal flow, and hence signaling messages must be protected not only on the link but also in the intermediate service nodes. Also, the deployment of MAPSec and IPSec is optional; hence if any service provider chooses to omit MAPSec/IPSec's deployment, the efforts of all other providers are wasted. Therefore, to completely protect MAP messages, MAPSec/IPSec must be used by every service provider.

With respect to wireline service nodes, while MAPSec/IPSec protects links between service nodes, there is no standardized method for protecting service nodes [7]. Remote and physical access to service nodes may be subject to operator's security policy and hence could be exploited (insider or outsider) if the network operator is lax with security. Accordingly, the core network suffers from the possibility of node impersonation, corruption of data sources, and service logic attacks. For example, unauthorized access to HLR could deactivate customers or activate customers not seen by the building system. Similarly, unauthorized access to MSC could cause outages for a large number of users in a given network area.

Corrupt data sources or service logic in service nodes have the added disadvantage of propagating this corruption to other service nodes in a cellular network [12−14] via signaling messages. This fact was recently confirmed by a security evaluation of cellular networks [13] that showed the damage potential of a compromised service node to be much greater than the damage potential of compromised signaling messages. Therefore, it is of utmost importance to standardize a scheme for protecting service nodes in the interest of not only preventing node impersonation attacks but also preventing the corruption from propagating to other service nodes.

In brief, the current generation core networks are lacking in security for all types of signaling messages, security for MAP signaling messages in service nodes, and a standardized method for protecting service nodes. To protect all types of signaling message protocols and ensure that messages are secured not only on the links between service nodes but also on the intermediate service nodes (that is, secured end to end), and prevent service logic corruption from propagating to other service nodes, the End-to-End Security (EndSec) protocol was proposed [13].

Because signaling message security essentially depends on security of data item values contained in these messages, EndSec focuses on securing data items. EndSec requires every data item to be signed by its source service nodes using public key encryption. By requiring signatures, if data items are corrupt by compromised intermediate service nodes en route, the compromised status of the service node is revealed to the service nodes receiving the corrupt data items. Revealing the compromised status of service nodes prevents corruption from propagating to other service nodes, because service nodes are unlikely to accept corrupt data items from compromised service nodes.

EndSec also prevents misrouting and node impersonation attacks by requiring every service node in a signal flow to embed the PATH taken by the signal flow in every EndSec message. Finally, EndSec introduces several control messages to handle and correct the detected corruption. Note that EndSec is not a standardized protocol.

Security Implications of Internet Connectivity

Internet connectivity introduces the biggest threat to the security of cellular networks. This is because cheap PC-based equipment with Internet connectivity can now access gateways connecting to the core network (of a cellular network). Therefore, any attack possible in the Internet can now filter into the core network via these gateways. For example, Internet connectivity was the reason for the slammer worm to filter into the E-911 service in Bellevue, Washington, making it completely unresponsive [15]. Other attacks that can filter into the core network from the Internet include spamming and phishing of short messages [16].

We expect low-bandwidth DoS attacks to be the most damaging attacks brought on by Internet connectivity [16,17,18]. These attacks demonstrate that by sending just 240 short messages per second, it is possible to saturate a cellular network and cause the MSC in charge of the region to be flooded and lose legitimate short messages per second. Likewise, it shows that it is possible to cause a specific user to lose short messages by flooding that user with a large number of messages, causing a buffer overflow. Such DoS attacks are possible because the short message delivery time in a cellular network is much greater than the short message submission time using Internet sites [17].

Also, short messages and voices services use the same radio channel, so contention for these limited resources may still occur and cause a loss of voice service. To avoid loss of voice services due to contention, separation of voice and data services on the radio network (of a cellular network) has been suggested [14]. However, such separation requires major standardization and overhaul of the cellular network and is therefore unlikely be implemented very soon. Other minor techniques such as queue management and resource provisioning have been suggested [17].

Though such solutions could reduce the impact of short message flooding, they cannot eliminate other types of low-bandwidth, DoS attacks such as attacks on connection setup and teardown of data services. The root cause for such DoS attacks from the Internet to the core network of a cellular network was identified as the difference in the design principles of these networks. Though the Internet makes no assumptions on the content of traffic and simply passes it on to the next node, the cellular network identifies the traffic content and provides a highly tailored service involving multiple service nodes for each type of traffic [18].

Until this gap is bridged, such attacks will continue, but bridging the gap itself is a major process because either the design of a cellular network must be changed to match the Internet design, or vice versa, which is unlikely to happen soon. Hence a temporary fix would be to secure the gateways connecting the Internet and core network. As a last note, Internet connectivity filters attacks not only into the core network, but also into the PSTN network. Hence PSTN gateways must also be guarded.

Security Implications of PSTN Connectivity

PSTN connectivity to cellular networks allows calls between the fixed and cellular networks. Though the PSTN was a closed network, the security-free SS7 protocol stack on which it is based was of no consequence. However, by connecting the PSTN to the core network that is in turn connected to the Internet, the largest open public network, the SS7-based PSTN network has "no security left" [19].

Because SS7 protocols are plaintext and have no authentication features, it is possible to introduce fake messages, eavesdrop, cause DoS by traffic overload, and incorrectly route signaling messages. Such introduction of SS7 messages into the PSTN network is very easily done using cheap PC-based equipment. Attacks in which calls for 800 and 900 numbers were rerouted to 911 servers so that legitimate calls were lost are documented [20]. Such attacks are more so possible due to the IP interface of the PSTN service nodes and Web-based control of these networks.

Because PSTN networks are to be outdated soon, there is no interest in updating these networks. So, they will remain "security free" until their usage is stopped [19].

So far, we have addressed the security and attacks on each aspect of a cellular network. But an attack that is common to all the aspects of a cellular network is the *cascading attack*. Next we detail the cascading attack and present the corresponding vulnerability assessment techniques.

4. CELLULAR NETWORK ATTACK TAXONOMY

In this part of the chapter, we present a cellular network specific attack taxonomy. This attack taxonomy is called the *three-dimensional taxonomy* because attacks are classified based on the following three dimensions: (1) adversary's physical access to the network when the attack is launched; (2) type of attack launched; and (3) vulnerability exploited to launch the attack.

The three-dimensional attack taxonomy was motivated by a *cellular network specific abstract model*, which is an atomic model of cellular network service nodes. It enables better study of interactions within a cellular network and aids in derivation of several insightful characteristics of attacks on the cellular network.

The abstract model not only led to the development of the three-dimensional attack taxonomy that has been instrumental in uncovering (1) *cascading attacks*, a type of attack in which the adversary targets a specific network location but attacks another location, which in turn propagates the attack to the target location, and (2) *cross-infrastructure cyber-attack*, a new breed of attack in which a cellular network may be attacked from the Internet [21]. In this part of the chapter we further detail the three-dimensional attack taxonomy and cellular network abstract model.

Abstract Model

The abstract model dissects functionality of a cellular network to the basic atomic level, allowing it to systematically isolate and identify vulnerabilities. Such identification of vulnerabilities allows attack classification based on vulnerabilities, and isolation of network functionality aids in extraction of interactions between network components, thereby revealing new vulnerabilities and attack characteristics.

Because service nodes in a cellular network comprise sophisticated *service logic* that performs numerous network functions, the abstract model logically divides the service logic into basic atomic units, called *agents* (represented by the elliptical shape in Figure 17.4). Each agent performs a single function. Service nodes also manage data, so the abstract model also logically divides data sources into data units specific to the agents they support. The abstract model also divides the data sources into *permanent* (represented by the rectangular shape in Figure 17.4) or *cached* (represented by the triangular shape in Figure 17.4) from other service nodes.

The abstract model developed for the CS domain is illustrated in Figure 17.4. It shows agents, permanent and cached data sources for the CS service nodes. For example, the *subscriber locator agent* in the HLR is the agent that tracks the subscriber location information. It receives and responds to location requests during an incoming call and stores a subscriber's location every time they move. This location information is stored in the *location data source*. Readers interested in further details may refer to [21,22].

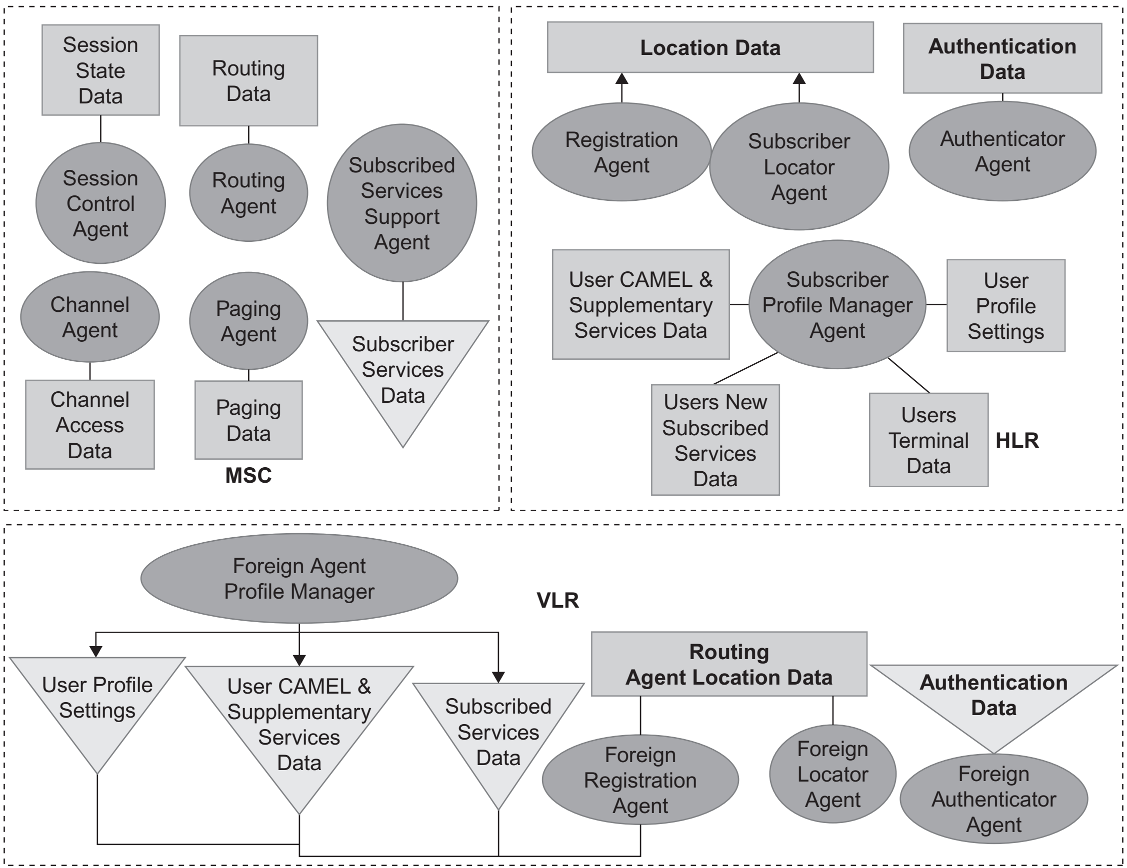

FIGURE 17.4 Abstract model of circuit-switched service nodes.

Abstract Model Findings

The abstract model led to many interesting findings. We outline them as follows:

Interactions

To study the network interactions, service nodes in signal flows (call delivery service) were replaced by their corresponding abstract model agents and data sources. Such an abstract-model – based signal flow based on the call delivery service is shown in Figure 17.5.

In studying the abstract model signal flow, it was observed that interactions happen (1) between agents typically using procedure calls containing data items; (2) between agents and data sources using queries containing data items; and (3) between agents belonging to different service nodes using signaling messages containing data items.

The common behavior in all these interactions is that they typically involve *data items* whose values are set or modified in agents or data source, or it involves data items passed between agents, data sources, or agents and data sources. Hence, the value of a data item not only can be corrupt in an agent or data source, it can also be easily passed on to other agents, resulting in propagation of corruption. This propagation of corruption is called the *cascading effect*, and attacks that exhibit this effect are called *cascading attacks*. In the following, we present a sample of the cascading attack.

Sample Cascading Attack

In this sample cascading attack, cascading due to corrupt data items and ultimately their service disruption are illustrated in Figure 17.6. Consider the call delivery service explained previously. Here the adversary may corrupt the *roaming number* data item (used to route the call) in the VLR. This corrupt *roaming number* is passed on in message PRN_ACK to the HLR, which in turn passes this information to the GMSC. The GMSC uses the incorrect *roaming number* to route the call to the incorrect MSC_B, instead of the correct MSC_A. This results in the caller losing the call or receiving a wrong-number call. Thus corruption cascades and results in service disruption.

The type of corruption that can cascade is *system-acceptable incorrect value corruption*, a type of corruption in which corrupt values taken on system-acceptable values, albeit incorrect values. Such a corruption can cause the roaming number to be incorrect but a system-acceptable value.

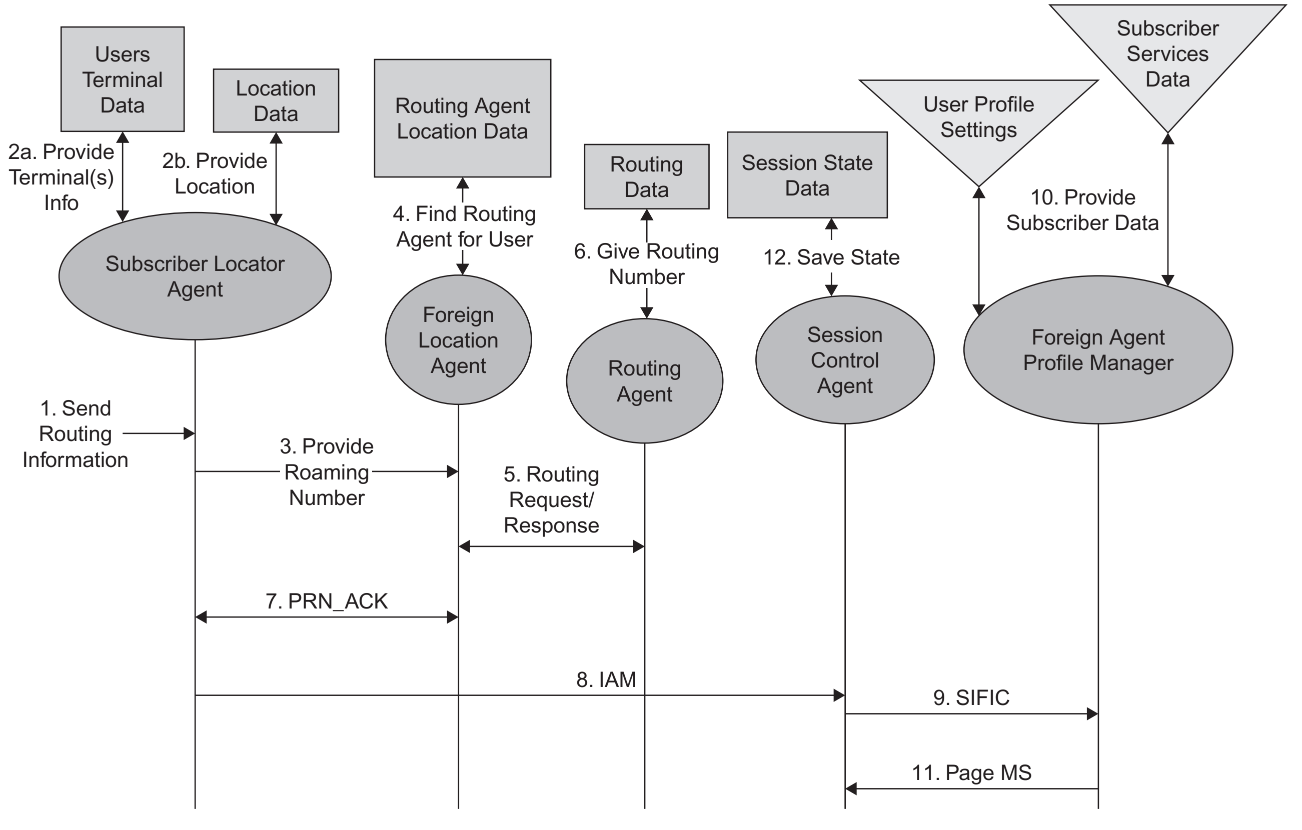

FIGURE 17.5 Abstract model-based signal flow for the call delivery service.

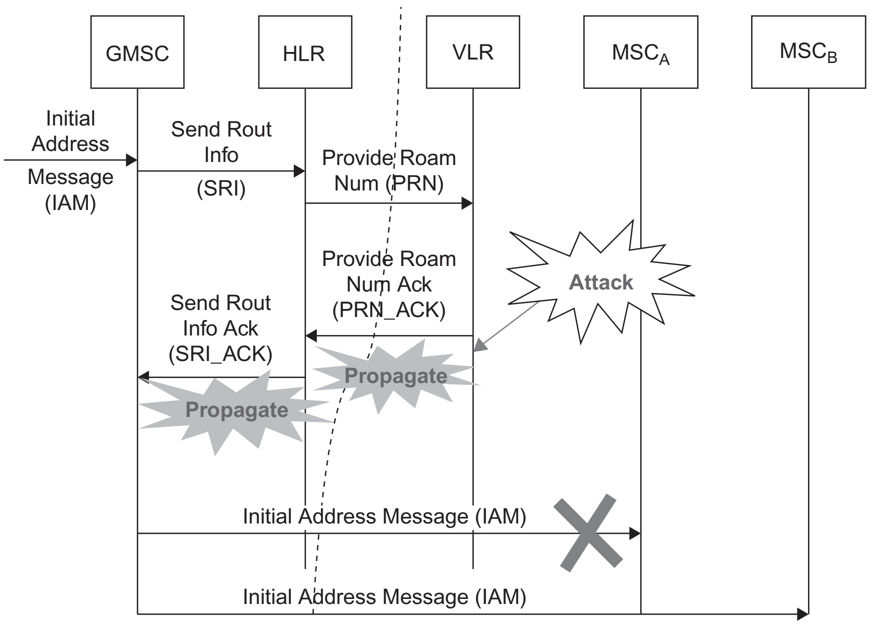

FIGURE 17.6 Sample cascading attacks in the call delivery service.

Note that it is easy to cause such system-acceptable incorrect value corruption due to the availability of Web sites that refer to proprietary working manuals of service nodes such as the VLR [23,24]. Such command insertion attacks have become highly commonplace, the most infamous being the telephone tapping of the Greek government and top-ranking civil servants [25].

Cross-Infrastructure Cyber Cascading Attacks

When cascading attacks cross into cellular networks from the Internet through *cross-network services*, they're called *cross-infrastructure cyber cascading attacks*. This attack is illustrated on the CFS in Figure 17.7.

As the CFS forwards calls based on the emails received, corruption is shown to propagate from the mail server to a call-forward (CF) server and finally to the MSC. In the attack, using any standard mail server vulnerabilities, the adversary may compromise the mail server and corrupt the email data source by deleting emails from people the victim is expecting to call. The CF server receives and caches incorrect email from the mail server.

When calls arrive for the subscriber, the call-forwarding service is triggered, and the MSC queries the CF server on how to forward the call. The CF server checks its incorrect email cache, and because there are no emails from the caller, it responds to the MSC to forward the call to the victim's voicemail when in reality the call should have been forwarded to the cellular device. Thus the effect of the attack on the mail server propagates to the CF service nodes. This is a classic example of a cross-infrastructure cyber cascading attack, whereby the adversary gains access to the cross-network server, and attacks by modifying data in the data source of the cross-network server. Note that it has become highly simplified to launch such attacks due to easy accessibility to the Internet and subscriber preference for Internet-based cross-network services.

Isolating Vulnerabilities

From the abstract model, the major vulnerable-to-attacks network components are: (1) data sources; (2) agents (more generally called service logic); and (3) signaling messages. By exploiting each of these vulnerabilities, data items that are crucial to the correct working of a cellular network can be corrupted, leading to ultimate service disruption through cascading effects.

In addition, the effect of corrupt signaling messages is different from the effect of corrupt data sources. By corrupting data items in a data source of a service node, all the subscribers attached to this service node may be affected. However, by corrupting a signaling message, only the subscribers (such as the caller and called party in case of call delivery service) associated with the message are affected. Likewise, corrupting the agent in the service node can affect all subscribers using the agent in the service node. Hence, in the three-dimensional taxonomy, a vulnerability exploited is considered as an attack dimension, since the effect on each vulnerability is different.

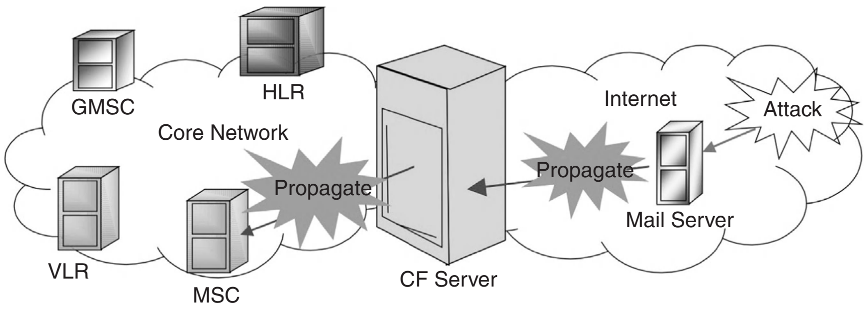

FIGURE 17.7 Cross-infrastructure cyber cascading attacks on call-forward service.

Likewise, the adversary's physical access to a cellular network also affects how the vulnerability is exploited and how the attack cascades. For example, consider the case when a subscriber has access to the air interface. The adversary can only affect messages on the air interface. Similarly, if the adversary has access to a service node, the data sources and service logic may be corrupted. Hence, in the three-dimensional taxonomy, the physical access is considered a category as it affects how the vulnerability is exploited and its ultimate effect on the subscriber.

Finally, the way the adversary chooses to launch an attack ultimately affects the service in a different way. Consider a passive attack such as *interception*. Here the service is not affected, but it can have a later effect on the subscriber, such as identity theft or loss of privacy. An active attack such as *interruption* can cause complete service disruption. Hence, in the three-dimensional taxonomy, the attack means are considered a category due the ultimate effect on service. In the next part of the chapter, we detail the cellular network specific three-dimensional taxonomy and the way the previously mentioned dimensions are incorporated (see checklist: "An Agenda For Action When Incorporating The Cellular Network Specific Three-Dimensional Attack Taxonomy").

Table 17.1 shows a sample tabulation of Level I attacks grouped in Case 1. For example, with Level I

An Agenda for Action when Incorporating the Cellular Network Specific Three-Dimensional Attack Taxonomy

The three dimensions in the taxonomy include Dimension I: Physical Access to the Network, Dimension II: Attack Categories and Dimension III: Vulnerability Exploited. In the following, we outline each dimension (check all tasks completed):

_____**1.** Dimension I—Physical Access to the Network: In this dimension, attacks are classified based on the adversary's level of physical access to a cellular network. Dimension I may be further classified into *single infrastructure attacks* (Level I—III) and *cross-infrastructure cyber-attacks* (Level IV—V):

_____**a.** *Level I: Access to air interface with physical device*. Here the adversary launches attacks via access to the radio access network using standard inexpensive "off-the-shelf" equipment [26]. Attacks include false base station attacks, eavesdropping, and man-in-the-middle attacks and correspond to attacks previously mentioned.

_____**b.** *Level II: Access to links connecting core service nodes*. Here the adversary has access to links connecting to core service nodes. Attacks include disrupting normal transmission of signaling messages and correspond to message corruption attacks previously mentioned.

_____**c.** *Level III: Access core service nodes*. In this case, the adversary could be an insider who managed to gain physical access to core service nodes. Attacks include editing the service logic or modifying data sources, such as subscriber data (profile, security and services) stored in the service node and corresponding to corrupt service logic, data source, and node impersonation attacks previously mentioned.

_____**d.** *Level IV: Access to links connecting the Internet and the core network service nodes*. This is a cross-infrastructure cyber-attack. Here the adversary has access to links connecting the core network and Internet service nodes. Attacks include editing and deleting signaling messages between the two networks. This level of attack is easier to achieve than Level II.

_____**e.** *Level V: Access to Internet servers or cross-network servers*: This is a cross-infrastructure cyber-attack. Here the adversary can cause damage by editing the service logic or modifying subscriber data (profile, security and services) stored

in the cross-network servers. Such an attack was previously outlined earlier in the chapter. This level of attack is easier to achieve than Level III.

_____**2.** Dimension II—Attack Type: In this dimension, attacks are classified based on the type of attack. The attack categories are based on Stallings [27] work in this area:

_____**a.** *Interception*. The adversary intercepts signaling messages on a cable (Level II access) but does not modify or delete them. This is a passive attack. This affects the privacy of the subscriber and the network operator. The adversary may use the data obtained from interception to analyze traffic and eliminate the competition provided by the network operator.

_____**b.** *Fabrication or replay*. In this case, the adversary inserts spurious messages, data, or service logic into the system, depending on the level of physical access. For example, via a Level II access, the adversary inserts fake signaling messages; and via a Level III access, the adversary inserts fake service logic or fake subscriber data into this system.

_____**c.** *Modification of resources*. Here the adversary modifies data, messages, or service logic. For example, via a Level II access, the adversary modifies signaling messages on the link; and via a Level III access, the adversary modifies service logic or data.

_____**d.** *Modification of resources*. Here the adversary modifies data, messages, or service logic. For example, via a Level II access, the adversary modifies signaling messages on the link; and via a Level III access, the adversary modifies service logic or data.

_____**e.** *Denial of service*. In this case, the adversary takes actions to overload a network results in legitimate subscribers not receiving service.

_____**f.** *Interruption*. Here the adversary causes an interruption by destroying data, messages, or service logic.

_____**3.** Dimension III—Vulnerability Exploited: In this dimension, attacks are classified based on the vulnerability exploited to cause the attack. Vulnerabilities exploited are explained as follows:

_____**a.** *Data*. The adversary attacks the data stored in the system. Damage is inflicted by modifying, inserting, and deleting the data stored in the system.

_____**b.** *Messages*. The adversary adds, modifies, deletes, or replays signaling messages.

_____**c.** *Service logic*. Here the adversary inflicts damage by attacking the service logic running in the various cellular core network service nodes.

_____**d.** *Attack classification*. In classifying attacks, we can group them according to *Case 1: Dimension I versus Dimension II*, and *Case 2: Dimension II versus Dimension III*. Note that the Dimension I versus Dimension III case can be transitively inferred from Case 1 and Case 2.

TABLE 17.1 Sample Case 1 Classification.

	Interception	Fabrication/Insertion	Modification of Resources	Denial of Service	Interruption
Level I	• Observe time, rate, length, source, and destination of victim's locations.	• Using modified cellular devices, the adversary can send spurious registration messages to the target network.	• With a modified base station and cellular devices, the adversary modifies conversations between subscribers and their base stations.	• The adversary can cause DoS by sending a large number of fake registration messages.	• Jam victims' traffic channels so that victims cannot access the channels.
	• With modified cellular devices, eavesdrop on victim.	• Likewise, using modified base stations, the adversary can signal victims to camp at their locations.			• Broadcast at a higher intensity than allowed, thereby hogging the bandwidth.

access an adversary causes interception attacks by observing traffic and eavesdropping. Likewise, fabrication attacks due to Level I access include sending spurious registration messages. Modification of resources due to Level I access includes modifying conversations in the radio access network. DoS due to Level I access occurs when a large number of fake registration messages are sent to keep the network busy so as to not provide service to legitimate subscribers. Finally, interruption attacks due to Level I access occur when adversaries jam the radio access channel so that legitimate subscribers cannot access the network. For further details on attack categories, refer to [22].

5. CELLULAR NETWORK VULNERABILITY ANALYSIS

Regardless of how attacks are launched, if attack actions cause a system-acceptable incorrect value corruption, the corruption propagates, leading to many unexpected cascading effects. To detect remote cascading effects and identify the origin of cascading attacks, cellular network vulnerability assessment tools were developed.

These tools, including the *Cellular Network Vulnerability Assessment Toolkit* (CAT) and the *advanced Cellular Network Vulnerability Assessment Toolkit* (aCAT) [12,28], receive the input from users regarding which data item(s) might be corrupted and output an attack graph. The CAT attack graph not only shows the network location and service where the corruption might originate, it also shows the various messages and service nodes through which the corruption propagates.

An attack graph is a diagrammatic representation of an attack on a real system. It shows various ways an adversary can break into a system or cause corruption and the various ways in which the corruption may propagate within the system. Attack graphs are typically produced manually by red teams and used by systems administrators for protection. CAT and aCAT attack graphs allow users to trace the effect of an attack through a network and determine its side effects, thereby making them the ultimate service disruption.

Cellular networks are at the nascent stage of development with respect to security, so it is necessary to evaluate security protocols before deploying them. Hence, aCAT can be extended with security protocol evaluation capabilities into a tool [13] called *Cellular Network Vulnerability Assessment Toolkit for evaluation* (eCAT). eCAT allows users to quantify the benefits of security solutions by removing attack effects from attack graphs based on the defenses provided. One major advantage of this approach is that solutions may be evaluated before expensive development and deployment.

It must be noted that developing such tools – CAT, aCAT, and eCAT – presented many challenges: (1) cellular networks are extremely complex systems; they comprise several types of service nodes and control protocols, contain hundreds of data elements, and support hundreds of services; hence developing such toolkits requires in-depth working knowledge of these systems; and (2) every cellular network deployment comprises a different physical configuration; toolkits must be immune to the diversity in physical configuration; and finally (3) attacks cascade in a network due to regular network activity as a result of dependencies; toolkits must be able to track the way that corruption cascades due to network dependencies.

The challenge of in-depth cellular network knowledge was overcome by incorporating the toolkits with cellular network specifications defined by the Third Generation Partnership Project (3GPP) and is available at no charge [29]. The 3GPP is a telecommunications standards body formed to produce, maintain, and develop globally applicable "technical specifications and technical reports" for a third-generation mobile system based on evolved GSM core networks and the radio access technologies that they support [24].

Usage of specifications allows handling of the diversity of physical configuration, as specifications detail the functional behavior and not the implementation structure of a cellular network. Specifications are written using simple flow-like diagrams called the Specification and Description Language (SDL) [30], and are referred to as *SDL specifications*. Equipment and service providers use these SDL specifications as the basis for their service implementations.

Corruption propagation is tracked by incorporating the toolkits with novel dependency and propagation models to trace the propagation of corruption. Finally, Boolean properties are superimposed on the propagation model to capture the impact of security solutions.

CAT is the first version of the toolkit developed for cellular network vulnerability assessment. CAT works by taking user input of *seeds* (data items directly corrupted by the adversary and the cascading effect of which leads to a goal) and *goals* (data parameters that are derived incorrectly due to the direct corruption of seeds by the adversary) and uses SDL specification to identify cascading attacks. However, SDL is limited in its expression of relationships and inexplicit in its assumptions and hence cannot capture all the dependencies; therefore CAT misses several cascading attacks.

To detect a complete set of cascading effects, CAT was enhanced with new features, to aCAT. The new features added to aCAT include (1) a network dependency model that explicitly specifies the exact dependencies in a cellular network; (2) infection propagation rules that identify the reasons that cause corruption to cascade; and (3) a small amount of expert knowledge. The network

dependency model and infection propagation rules may be applied to SDL specifications and help alleviate their limited expression capability. The expert knowledge helps capture the inexplicit assumptions made by SDL.

In applying these features, aCAT captures all those dependencies that were previously unknown to CAT, and thereby aCAT was able to detect a complete set of cascading effects. Through extensive testing of aCAT, several interesting attacks were found and the areas where SDL is lacking was identified.

To enable evaluation of new security protocols, aCAT was extended to eCAT. eCAT uses Boolean probabilities in attack graphs to detect whether a given security protocol can eliminate a certain cascading effect. Given a security protocol, eCAT can measure effective coverage, identify the types of required security mechanisms to protect the network, and identify the most vulnerable network areas. eCAT was also used to evaluate MAPSec, the new standardized cellular network security protocol. Results from MAPSec's evaluation gave insights into MAPSec's performance and the network's vulnerabilities. In the following, we detail each toolkit.

Cellular Network Vulnerability Assessment Toolkit (CAT)

In this part of the chapter, we present an overview of CAT and its many features. CAT is implemented using the Java programming language. It is made up of a number of subsystems (as shown in Figure 17.8). The *knowledge base* contains the cellular network knowledge obtained from SDL specifications. SDL specifications contain simple flowchart-like diagrams. The flowcharts are converted into data in the *knowledge base*. The *integrated data structure* is similar to that of the knowledge base; it holds intermediate attack graph results.

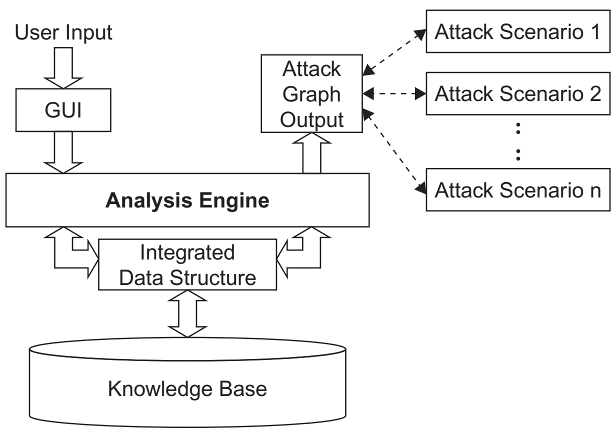

FIGURE 17.8 Architecture of CAT.

The GUI subsystem takes user input in the form of seeds and goals. The analysis engine contains algorithms (forward and midpoint) incorporated with cascading effect detection rules. It explores the possibility of the user input *seed* leading to the cascading effect of the user input *goal*, using the knowledge base, and outputs the cascading attack in the form of attack graphs.

Using these attack graphs, realistic attack scenarios may be derived. Attack scenarios explain the effect of the attack on the subscriber in a realistic setting. Each attack graph may have multiple interpretations and give rise to multiple scenarios. Each scenario gives a different perspective on how the attack may affect the subscriber.

Cascading Effect Detection Rules

The Cascading Effect Detection Rules were defined to extract cascading effects from the SDL specifications contained in the knowledge base. They are incorporated into the algorithms in the analysis engine. These rules define what constitutes propagation of corruption from a signaling message to a block, and vice versa, and propagation of corruption within a service node. For example, when a service node receives a signaling message with a corrupt data item and stores the data item, it constitutes propagation of corruption from a signaling message to a block. Note that these rules are high level.

Attack Graph

The CAT attack graph may be defined as a state transition showing the paths through a system, starting with the conditions of the attack, followed by attack action, and ending with its cascading effects. In Figure 17.9, we present the CAT attack graph output, which was built using user input of *ISDN Bearer Capability* as a seed and *Bearer Service* as goal. The attack graph constitutes nodes and edges. Nodes represent states in the network with respect to the attack, and *edges* represent network state transitions. For description purposes, each node has been given a node label followed by an alphabet, and the attack graph has been divided into layers.

Nodes may be broadly classified as *conditions, actions*, and *goals*, with the conditions of the attack occurring at the lowest layer and the final cascading effect at the highest layer. In the following, we detail each node type.

Condition Nodes

Nodes at the lowest layer typically correspond to the conditions that must exist for the attack to occur. These condition nodes directly follow from the taxonomy. They are an adversary's physical access, target service node, and vulnerability exploited. For example, the adversary

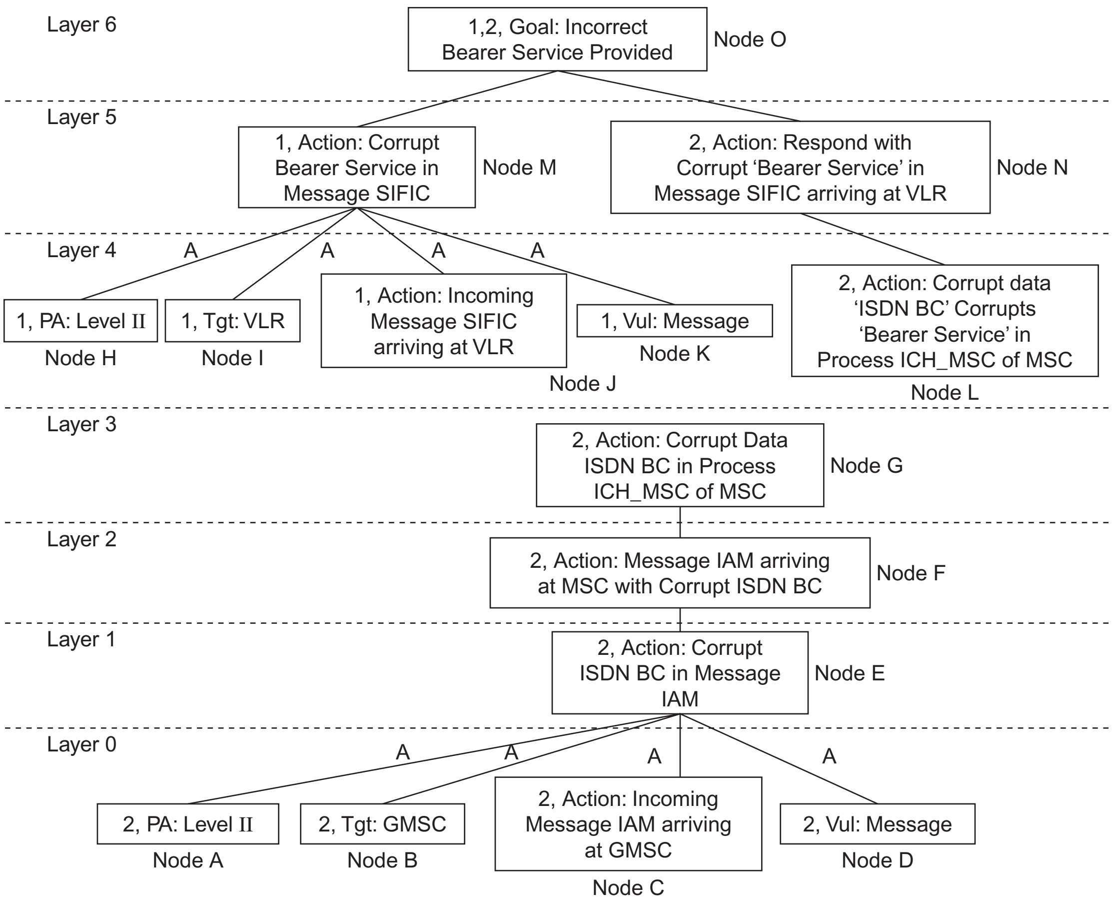

FIGURE 17.9 CAT attack graph output.

has access to links connecting to the GMSC service node, that is, Level II physical access; this is represented as Node A in the attack graph. Likewise, the adversary corrupts data item ISDN Bearer Capability in the IAM message arriving at the GMSC. Hence the target of the attack is the GMSC and is represented by Node B. Similarly, the adversary exploits vulnerabilities in a message (IAM); and, this is represented by Node D in the attack graph.

The CAT attack graphs show all the possible conditions for an attack to happen. In other words, we see not only the corruption due to the seed ISDN Bearer Capability in the signaling message, but also IAM arriving at the GMSC. But, there are also other possibilities, such as the corruption of the goal Bearer Service in the signaling message SIFIC, represented by Node M.

Action Nodes

Nodes at higher layers are actions that typically correspond to effects of the attack propagating through the network. Effects typically include propagation of corruption between service nodes, such as from MSC to VLR (Node N), propagation of corruption within service nodes such as ISDN Bearer Capability corrupting Bearer Service (Node L), and so on. Actions may further be classified as adversary actions, normal network operations, or normal subscriber activities. Adversary actions include insertion, corruption, or deletion of data, signaling messages, or service logic represented by Node E. Normal network operations include sending (Node N) and receiving signaling messages (Node E). Subscriber activity may include updating personal data or initiating service.

Goal Nodes

Goal nodes typically occur at the highest layer of the attack graph. They indicate corruption of the goal items due to the direct corruption of seeds by the adversary (Node A).

Edges

In our graph, edges represent network transitions due to both normal network actions and adversary actions. Edges help show the global network view of adversary action. This is the uniqueness of our attack graph.

Transitions due to adversary action are indicated by an edge marked by the letter A (edges connecting Layer 0 and Layer 1). By inclusion of normal network transitions in addition to the transitions caused by the adversary, our attack graph shows not only the adversary's activity but also the *global network view of the adversary's action*. This is a unique feature of the attack graph.

Trees

In the graph, trees are distinguished by the tree numbers assigned to its nodes. For example, all the nodes marked with number 2 belong to Tree 2 of the graph. Some nodes in the graph belong to multiple trees. Tree numbers are used to distinguish between AND and OR nodes in the graph. Nodes at a particular layer with the same tree number(s) are AND nodes. For example, at Layer 4, Nodes H, I, J, and K are AND nodes; they all must occur for Node M at Layer 5 to occur. Multiple tree numbers on a node are called OR nodes. The OR node may be arrived at using alternate ways. For example, Node O at Layer 6 is an OR node, the network state indicated by Node O may be arrived at from Node M or Node N.

Each attack tree shows the attack effects due to corruption of a seed at a specific network location (such as signaling message or process in a block). For example, Tree 1 shows the attack due to the corruption of the seed Bearer Service at the VLR. Tree 2 shows the propagation of the seed ISDN Bearer Capability in the signaling message IAM. These trees show that the vulnerability of a cellular network is not limited to one place but can be realized due to the corruption of data in many network locations.

In constructing the attack graph, CAT assumes that an adversary has all the necessary conditions for launching the attack. The CAT attack graph format is well suited to cellular networks because data propagates through the network in various forms during the normal operation of a network; thus an attack that corrupts a data item manifests itself as the corruption of a different data item in a different part of the network after some network operations take place.

Attack Scenario Derivation

The CAT attack graph is in cellular network semantics, and realistic attack scenarios may be derived to understand the implications of the attack graph. Here we detail the principles involved in the derivation of realistic attack scenarios:

End-User effect

Goal node(s) are used to infer the end effect of the attack on the subscriber. According to the goal node in Figure 17.9, the SIFIC message to the VLR has incorrect goal item Bearer Service. The SIFIC message is used to inform the VLR the calling party's preferences such as voice channel requirements and request the VLR to set up the call based on the calling party and receiving party preferences.

If the calling party's preferences (such as Bearer Service) are incorrect, the call setup by the VLR is incompatible with the calling party, and the communication is ineffective (garbled speech). From the goal node, it can be inferred that Alice, the receiver of the call, is unable to communicate effectively with Bob, the caller, because Alice can only hear garbled speech from Bob's side.

Origin of Attack

Nodes at Layer 0 indicate the origin of the attack, and hence the location of the attack may be inferred. The speech attack may originate at the signaling messages IAM, or the VLR service node.

Attack Propagation and Side Effects

Nodes At All Other Layers Show The Propagation Of Corruption Across The Various Service Nodes In The Network. From Other Layers In Figure 17.9, It Can Be Inferred That The Seed Is The ISDN Bearer Capability And The Attack Spreads From The MSC To The VLR.

Example Attack Scenario

Using these guidelines, an attack scenario may be derived as follows. Trudy, the adversary, corrupts the ISDN Bearer Capability of Bob, the victim, at the IAM message arriving at the GMSC. The GMSC propagates this corruption to the MSC, which computes, and hence corrupts, the Bearer Service. The corrupt Bearer Service is passed on to the VLR, which sets up the call between Bob, the caller, and Alice, the receiver. Bob and Alice cannot communicate effectively because Alice is unable to understand Bob.

Though CAT has detected several cascading attacks, its output to a great extent depends on SDL's ability to capture data dependencies. SDL is limited in its expression capability in the sense that it does not always accurately capture the relationship between data items, and in many cases, SDL does even specify the relationship. Without these details CAT may miss some cascading effects due to loss of data relationships. CAT's output to a minor extent also depends on user input in the sense that to accurately capture all the cascading effect of a seed, the user's input must comprise all the seeds that can occur in the cascading effect; otherwise the exact

cascading effect is not captured. To alleviate CAT's inadequacies, aCAT was developed.

Advanced Cellular Network Vulnerability Assessment Toolkit (aCAT)

In this section, we present aCAT, an extension of CAT with enhanced features. These enhanced features include (1) incorporating expert knowledge to compensate for the lacking caused by SDL's inexplicit assumptions; expert knowledge added to the knowledge base with the SDL specifications; (2) defining a network dependency model that accurately captures the dependencies in a cellular network; the network dependency model is used to format the data in knowledge base, thereby clarifying the nature of the network dependency; and (3) defining infection propagation rules that define fine-grained rules to detect cascading attacks; these infection propagation rules are incorporated into the analysis engine, which comprises the forward, reverse, and combinatory algorithms. aCAT is also improved in terms of its user input requirements. It requires as input either seeds or goals, whereas CAT required both seeds and goals.

In principle, cascading attacks are the result of propagation of corruption between network components (such as signaling messages, caches, local variables, and service logic) due to dependencies that exist between these network components. Hence, to uncover these attacks, the network dependency model and infection propagation (IP) rules were defined. In the following, we detail the network dependency model and infection propagation model using Figure 17.10.

Network Dependency Model

The network dependency model accurately defines fine-grained dependencies between the various network components. Given that service nodes comprise agents and data sources (from the abstract model), the dependencies are defined as follows. In interagent dependency, agents communicate with each other using agent invocations (as shown by 6 in Figure 17.10) containing data items. Thus, agents are related to each other through data items. Likewise, in agent to data source dependency, agents communicate with data sources using Read and Write operations containing data items. Therefore, agents and data items are related to each other through data items. Within agents, derivative dependencies define relationships between data items. Here data items are used as input to derive data items using derivation operations such as AND, OR operations. Therefore, data items are related to each other through derivation operation. For further detail on the network dependency model, refer to [12].

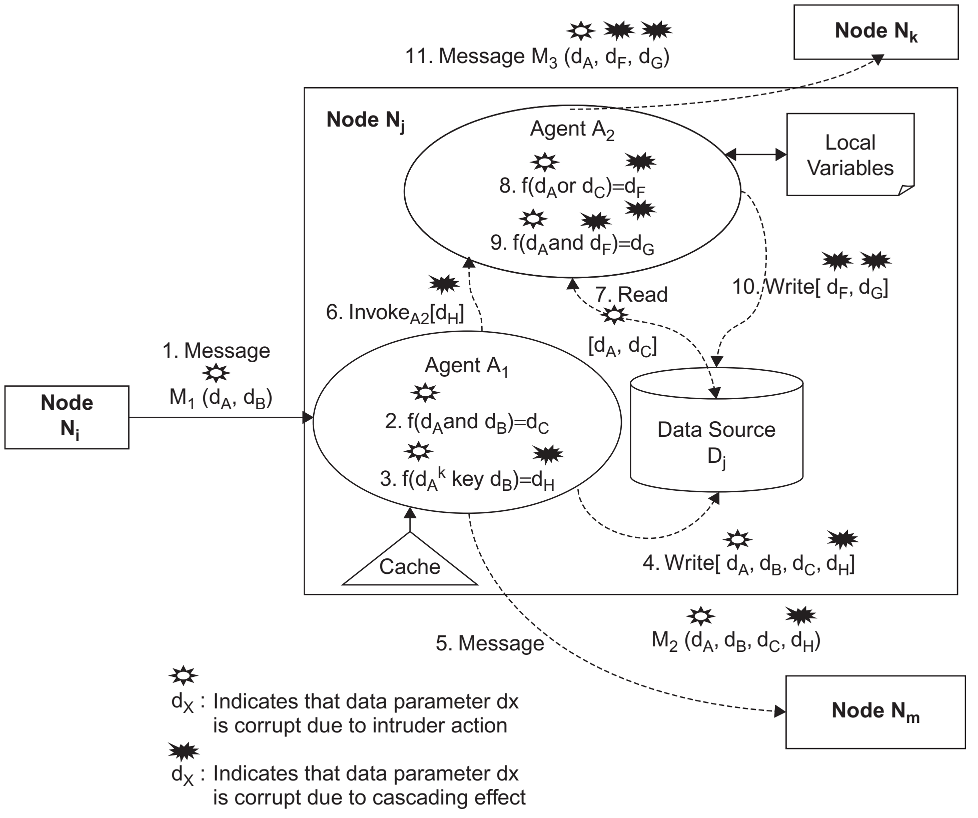

FIGURE 17.10 Network dependency model.

Infection Propagation (IP) Rules

These are finegrained rules to detect cascading effects. They are incorporated into the algorithms in the analysis engine. An example of the IP rule is that an output data item in the AND dependency is corrupt only if both the input data items are corrupt (as shown by 9 in Figure 17.10). Likewise, an output data item in the OR dependency is corrupt if a single input data item is corrupt (as shown by 8 in Figure 17.10). Similarly, corruption propagates between agents when the data item used to invoke the agent is corrupt, and the same data item is used as an input in the derivative dependency whose output may be corrupt (as shown by 6, 8 in Figure 17.10). Accordingly, corruption propagates from an agent to a data source if the data item written to the data source is corrupt (as shown by 4 in Figure 17.10). Finally, corruption propagates between service nodes if a data item used in the signaling message between the service nodes is corrupt, and the corrupt data item is used to derive corrupt output items or the corrupt data item is stored in the data source (as shown by 1, 3 or 1, 4 in Figure 17.10) [12].

With such a fine-grained dependency model and infection propagation rules, aCAT was very successful in identifying cascading attacks in several key services offered by a cellular network, and it was found that aCAT can indeed identify a better set of cascading effects in comparison to CAT. aCAT has also detected several interesting and unforeseen cascading attacks that are subtle and difficult to identify by other means. These newly identified cascading attacks include the alerting attack, power-off/power-on attack, mixed identity attack, call redirection attack, and missed calls attack.

Alerting Attack

In the following we detail aCAT's output, a cascading attack called the *alerting attack*, shown in Figure 17.11. From goal nodes (Node A at Level 5, and Node C at Level 4) in the alerting attack, it can be inferred that the Page message has incorrect data item *page type*. The Page message is used to inform subscribers of the arrival of incoming calls, and "page type" indicates the type of call. "Page type" must be compatible with the subscriber's mobile station or else the subscriber is not alerted. From the goal node it may be inferred that Alice, a subscriber of the system, is not alerted on the arrival of an incoming call and hence does not receive incoming calls. This attack is subtle to detect because network administrators find that the network processes the incoming call correctly and that the subscriber is alerted correctly. They might not find that this alerting pattern is incompatible with the mobile station itself.

Also, nodes at Level 0 indicate the origin of the attack as signaling messages SRI, PRN, the service nodes VLR, or the HLR. From the other levels it may be inferred that the seed is the *alerting pattern* that the adversary corrupts in the SRI message and the attack spreads from the HLR to the VLR and from the VLR to the MSC. For more details on these attacks, refer to [12].

Cellular Network Vulnerability Assessment Toolkit for Evaluation (eCAT)

In this part of the chapter, we present eCAT an extension to aCAT. eCAT was developed to evaluate new security protocols before their deployment. Though the design goals and threat model of these security protocols are common knowledge, eCAT was designed to find (1) the effective protection coverage of these security protocols in terms of percentage of attacks prevented; (2) the other kinds of security schemes required to tackle the attacks that can evade the security protocol under observation; and (3) the most vulnerable network areas (also called *hotspots*) [13].

eCAT computes security protocol coverage using attack graphs generated by aCAT and Boolean probabilities in a process called *attack graph marking* and quantifies the coverage using *coverage measurement formulas* (CMF). Attack graph marking also identifies network hotspots and exposes if the security protocol being evaluated protects these hotspots. eCAT was also used to evaluate MAPSec, as it is a relatively new protocol, and evaluation results would aid network operators.

Boolean Probabilities

Boolean probabilities are used in attack graphs to distinguish between nodes eliminated (denoted by 0, or shaded node in attack graph) and nodes existing (denoted by 1, or unshaded node in attack graph) due to the security protocol under evaluation. By computing Boolean probabilities for each node in the attack graph, eCAT can extract the attack effects that may be eliminated by the security protocol under evaluation.

Attack Graph Marking

To mark attack graphs, user input of Boolean probabilities must be provided for Layer 0 nodes. For example, if the security protocol under evaluation is MAPSec, then because MAPSec provides security on links between nodes, it eliminates Level 2 physical access. For example, consider the attack graph generated by eCAT shown in Figure 17.12. Here, Node 5 is set to 0, while all other nodes are set to 1.

eCAT uses the input from Layer 0 nodes to compute the Boolean probabilities for the rest of the nodes starting from Layer 1 and moving upward. For example, the

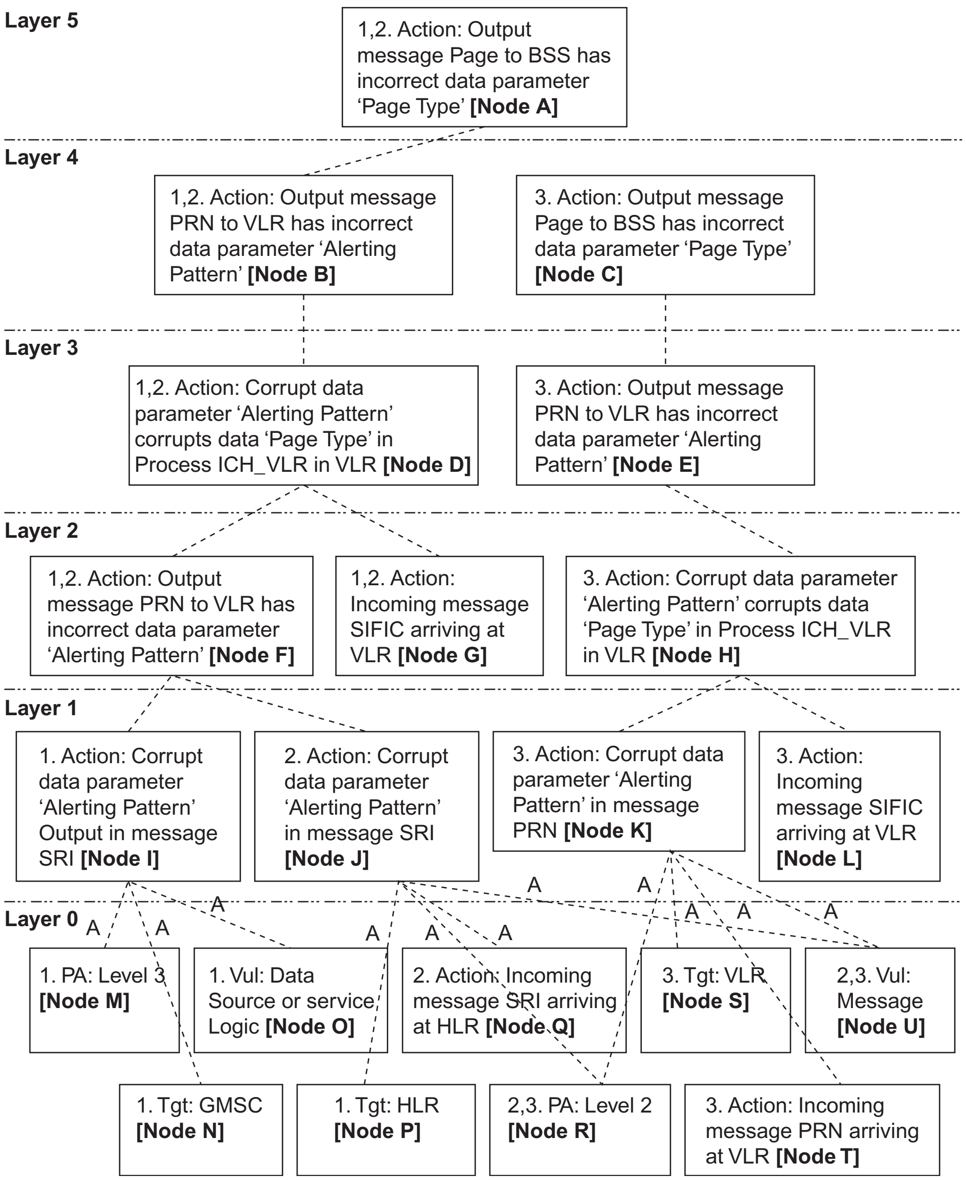

FIGURE 17.11 Attack graph for alerting attack.

Boolean probability of the AND node (Node 18) is the product of all the nodes in the previous layer with the same tree number. Because Node 5 has the same tree number as Node 18, and Node 5's Boolean probability is 0, Node 18's Boolean probability is also 0. This process of marking attack graphs is continued until Boolean probability of all the nodes is computed till the topmost layer.

Hotspots

Graph marking also marks the network hotspots in the attack graph. With respect to the attack graph, hotspots are the Layer 0 nodes with the highest tree number count. For example in Figure 17.12, Node 3 and Node 4 are the hotspots. A high tree number count indicates an increased attractiveness of the network location to adversaries. This is because by breaking into the network location indicated by the hotspot node, the adversary has a higher likelihood of success and can cause the greatest amount of damage.

Extensive testing of eCAT on several of the network services using MAPSec has revealed hotspots to be "Data Sources and Service Logic." This is because a corrupt data source or service logic may be used by many different services and hence cause many varied cascading effects, spawning a large number of attacks (indicated by multiple trees in attack graphs). Thus attacks that occur due to exploiting service logic and data source vulnerabilities constitute a major portion of the networkwide vulnerabilities and so a major problem. In other words, by exploiting service logic and data sources, the likelihood

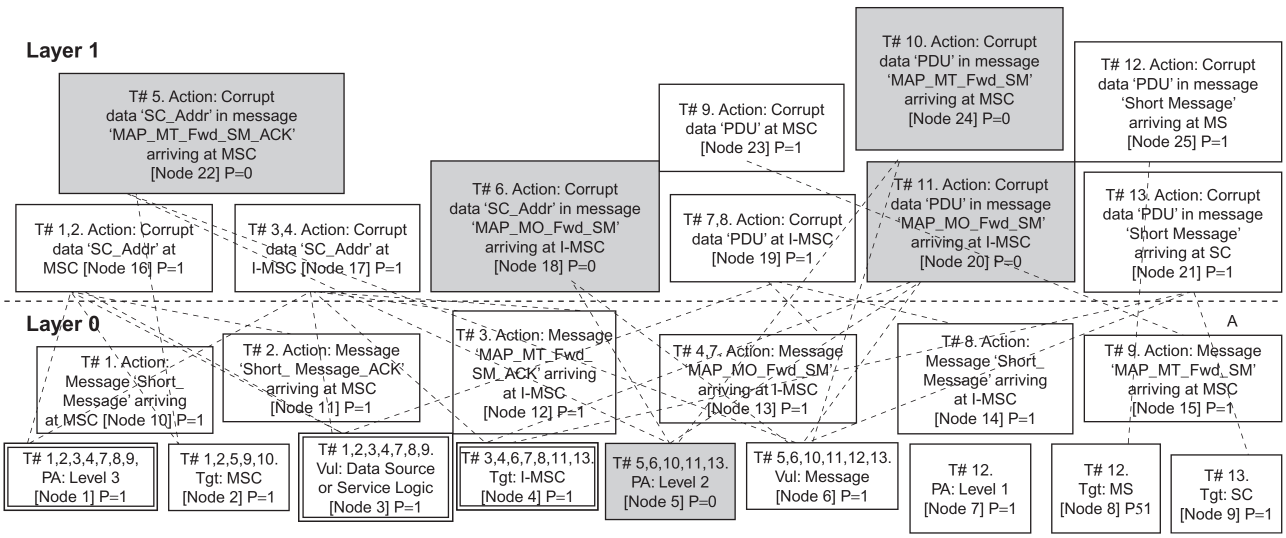

FIGURE 17.12 Fragment of a marked attack graph generated by eCAT.

of attack success is very high. Therefore data source and service logic protection mechanisms must be deployed. It must be noted that MAPSec protects neither service logic nor data sources; rather, it protects MAP messages.

Coverage Measurement Formulas

The CMF comprises the following set of three formulas to capture the coverage of security protocols: (1) *effective coverage*, to capture the average effective number of attacks eliminated by the security protocol; the higher the value of Effective Coverage the greater the protection the security protocol; (2) *deployment coverage*, to capture the coverage of protocol deployments; and (3) *attack coverage*, to capture the attack coverage provided by the security protocol; the higher this value, the greater is the security solution's efficacy in eliminating a large number of attacks on the network.

Extensive use of CMF on several of the network services has revealed that MAPSec has an average network-wide attack coverage of 33%. This may be attributed to the fact that message corruption has a low spawning effect. Typically a single message corruption causes a single attack, since messages are typically used by a single service. Hence MAPSec is a solution to a small portion of the total network vulnerabilities.

Finally, in evaluating MAPSec using eCAT, it was observed that though MAPSec is 100% effective in preventing MAP message attacks, it cannot prevent a successfully launched attack from cascading. For MAPSec to be truly successful, every leg of the MAP message transport must be secured using MAPSec. However, the overhead for deploying MAPSec can be high, in terms of both processing load and monetary investment. Also, as MAP messages travel through third-party networks en route to their destinations, the risk level of attacks without MAPSec is very high. Hence, MAPSec is vital to protect MAP messages.

In conclusion, because MAPSec can protect against only 33% of attacks, it alone is insufficient to protect the network. A complete protection scheme for the network must include data source and service logic protection.

6. SUMMARY

Next to the Internet, cellular networks are the most highly used communication network. It is also the most vulnerable, with inadequate security measures making it a most attractive target to adversaries that want to cause communication outages during emergencies. As cellular networks are moving in the direction of the Internet, becoming an amalgamation of several types of diverse networks, more attention must be paid to securing these networks. A push from government agencies requiring mandatory security standards for operating cellular networks would be just the momentum needed to securing these networks.

Of all the attacks discussed in this chapter, cascading attacks have the most potential to stealthily cause major network misoperation. At present there is no standardized scheme to protect from such attacks. EndSec is a good solution for protecting from cascading attacks, since it requires every data item to be signed by the source service node. Because service nodes are unlikely to corrupt data items and they are to be accounted for by their signatures, the possibility of cascading attacks

is greatly reduced. EndSec has the added advantage of providing end-to-end security for all types of signaling messages. Hence, standardizing EndSec and mandating its deployment would be a good step toward securing the network.

Both Internet and PSTN connectivity are the open gateways that adversaries can use to gain access and attack the network. Because the PSTN's security is not going to be improved, at least its gateway to the core network must be adequately secured. Likewise, since neither the Internet's design nor security will be changed to suit a cellular network, at least its gateways to the core network must be adequately secured.

Finally, because a cellular network is an amalgamation of many diverse networks, it has too many vulnerable points. Hence, the future design of the network must be planned to reduce the number of vulnerable network points and reduce the number of service nodes that participate in servicing the subscriber, thereby reducing the number of points from which an adversary may attack.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Cellular networks are high-speed, high-capacity voice and data communication networks with enhanced multimedia and seamless roaming capabilities for supporting cellular devices.
2. True or False? The current cellular network is an evolution of the early-generation cellular networks that were built for optimal performance.
3. True or False? It would seem that attacks on the radio access network could not easily happen, because anyone with a transmitter/receiver could capture these signals.
4. True or False? Though the current generation of a cellular network has seen many security improvements in the radio access network, the security of the core network is not as improved.
5. True or False? Internet connectivity introduces the biggest threat to the security of cellular networks.

Multiple Choice

1. Cellular networks are organized as collections of interconnected:
   A. Message Integrity Codes (MIC)
   B. Temporal Key Integrity Protocols (TKIP)
   C. Application Program Interfaces
   D. Network Areas
   E. Extensible Authentication Protocol (EAP) framework
2. The core network is facilitated by network servers, which are also called?
   A. Middle Layers
   B. Network Layers
   C. Transport Layers
   D. Service Nodes
   E. All of the above
3. What is a basic service in the circuit-switched domain?
   A. Secure on-demand routing protocol service
   B. Taxonomy service
   C. Caller delivery service
   D. Authenticated Routing for Ad hoc Networks (ARAN) service
   E. Destination-Sequenced Distance Vector (DSDV) routing service
4. The cloning of cellular devices to utilize the network resources without paying; and cloning BSs to entice users to camp at the cloned BS in an attack, is called a:
   A. False base station attack.
   B. Privacy attack.
   C. Eavesdropping attack
   D. Man-in-the-Middle Attack.
   E. Passive attack.
5. What introduces the biggest threat to the security of cellular networks?
   A. HELLO Flood connectivity.
   B. Denial-of-service attack connectivity.
   C. Internet connectivity.
   D. Sybil connectivity.
   E. All of the above.

1. RFID INTRODUCTION

Generally, an RFID system consists of three basic components: RFID tags, RFID readers, and a back-end database:

- *RFID tags or RFID transponders.* These are the data carriers attached to objects. A typical RFID tag contains information about the attached object, such as an identifier (ID) of the object and other related properties of the object that may help to identify and describe it.
- *The RFID reader or the RFID transceiver*. These devices can read information from tags and may write information into tags if the tags are rewritable.
- *Back-end database.* This is the data repository responsible for the management of data related to the tags and business transactions, such as ID, object properties, reading locations, reading time, and so on.

RFID System Architecture

RFID systems' architecture is illustrated in Figure 18.1. Tags are attached to or embedded in objects to identify or annotate them. An RFID reader send out signals to a tag for requesting information stored on the tag. The tag responses to the request by sending back the appropriate information. With the data from the back-end database, applications can then use the information from the tag to proceed with the business transaction related to the object.

Tags

In RFID systems, objects are identified or described by information on RFID tags attached to the objects. An RFID tag basically consists of a microchip that is used for data storage and computation and a coupling element for communicating with the RFID reader via radio frequency communication, such as an antenna. Some tags may also have an on-board battery to supply a limited amount of power.

RFID tags can respond to radio frequencies sent out by RFID readers. On receiving the radio signals from a RFID reader, an RFID tag either send back the requested data stored on the tag or write the data into the tag, if the tag is rewritable. Because radio signals are used, RFID tags do not require line of sight to connect with the reader and precise positioning, as barcodes do. Tags may also generate a certain amount of electronic power from the radio signals they receive, to power the computation and transmission of data.

RFID tags can be classified based on four main criteria: power source, type of memory, computational power, and functionality.

A basic and important classification criterion of RFID tags is to classify tags based on power source. Tags can be categorized into three classes: active, semi-active, and passive RFID tags.

Active RFID tags have on-board power sources, such as batteries. Active RFID tags can proactively send radio signals to an RFID reader and possibly to other tags [1]

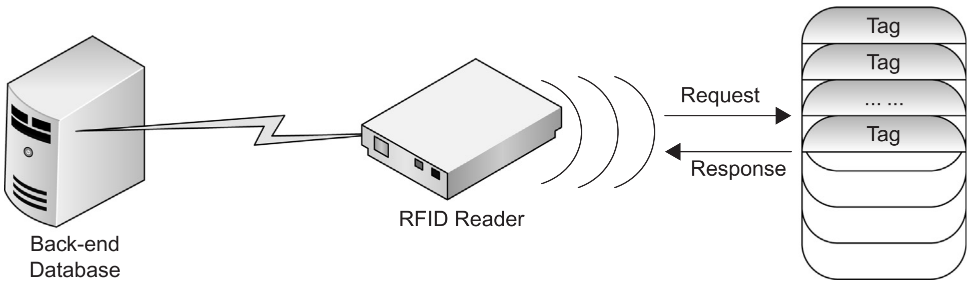

FIGURE 18.1 RFID system architecture.

as well. Compared with tags without on-board power, active tags have longer transmission range and are more reliable. Active tags can work in the absence of an RFID reader. On the other hand, the on-board power supply also increases the costs of active tags.

Semi-active RFID tags also have on-board power sources for powering their microchips, but they use RFID readers' energy field for actually transmitting their data [2] when responding to the incoming transmissions. Semi-active tags have the middle transmission range and cost.

Passive RFID tags do not have internal power sources and cannot initiate any communications. Passive RFID tags generate power from radio signals sent out by an RFID reader in the course of communication. Thus passive RFID tags can only work in the presence of an RFID reader. Passive tags have the shortest transmission range and the cheapest cost. The differences of active, semi-active and passive tags are shown in Table 18.1.

TABLE 18.1 Tags Classified by Power Source.

Power Source	Active Tags	Semiactive Tags	Passive Tags
On-board power supply	Yes	Yes	No
Transmission range	Long	Medium	Short
Communication pattern	Proactive	Passive	Passive
Cost	Expensive	Medium	Cheap

RFID tags can be classified into three categories according to the type of memory that a tag uses: read-only tags, write-once/read-many tags, and fully rewritable tags. The information on read-only tags cannot be changed in the life-cycle of the tags. Write-once/read-many tags can be initialized with application-specific information. The information on fully rewritable tags can be rewritten many times by an RFID reader.

According to the computational power, RFID tags can be classified into three categories: basic tags, symmetric-key tags, and public-key tags. Basic tags do not have the ability to perform cryptography computation. Symmetric-key tags and public-key tags have the ability to perform symmetric-key and public—key cryptography computation, respectively.

RFID tags can also be classified according to their functionality. The MIT Auto-ID Center defined five classes of tags according to their functionality in 2003 [3]: Class 0, Class 1, Class 2, Class 3, and Class 4 tags. Every class has different functions and different requirements for tag memory and power resource. Class 0 tags are passive and do not contain any memory. They only announce their presence and offer electronic article surveillance (EAS) functionality. Class 1 tags are typically passive. They have read-only or write-once/read-many memory and can only offer identification functionality. Class 2 tags are mostly semi-active and active. They have fully rewritable memory and can offer data-logging functionality. Class 3 tags are semi-active and active tags. They contain on-board environmental sensors that can record temperature, acceleration, motion, or radiation and require fully rewritable memory. Class 4 tags are active tags and have fully rewritable memory. They can establish ad hoc wireless networks with other tags because they are equipped with wireless networking components.

RFID Readers

An RFID reader (transceiver) is a device used to read information from and possibly also write information into RFID tags. An RFID reader is normally connected to a back-end database for sending information to that database for further processing.

An RFID reader consists of two key functional modules: a high-frequency (HF) interface and a control unit. The HF interface can perform three functions: generating the transmission power to activate the tags, modulating the signals for sending requests to RFID tags, and receiving and demodulating signals received from tags. The control unit of an RFID reader has also three basic

functions: controlling the communication between the RFID reader and RFID tags, encoding and decoding signals, and communicating with the back-end server for sending information to the back-end database or executing the commands from the back-end server. The control unit can perform more functions in the case of complex RFID systems, such as executing anticollision algorithms in the cause of communicating with multitags, encrypting requests sent by the RFID reader and decrypting responses received from tags, and performing the authentication between RFID readers and RFID tags [4].

RFID readers can provide high-speed tag scanning. Hundreds of objects can be dealt with by a single reader within a second; thus it is scalable enough for applications such as supply chain management, where a large number of objects need to be dealt with frequently. RFID readers need only to be placed at every entrance and exit. When products enter or leave the designated area by passing through an entrance or exit, the RFID readers can instantly identify the products and send the necessary information to the back-end database for further processing.

Back-End Database

The back-end database is in the back-end server that manages the information related to the tags in an RFID system. Every object's information can be stored as a record in the database, and the information on the tag attached to the object can serve as a pointer to the record.

The connection between an RFID reader and a back-end database can be assumed as secure, no matter via wireless link or not, because constraints for readers are not very tight and security solutions such as SSL/TLS can be implemented for them [5].

RFID Standards

Currently, as different frequencies are used for RFID systems in various countries and many standards are adopted for different kinds of application, there is no agreement on a universal standard that's accepted by all parties. Several kinds of RFID standards [6] are being used today. These standards include contactless smart cards, item management tags, RFID systems for animal identification, and electronic product code (EPC) tags. These standards specify the physical layer and the link layer characteristics of RFID systems but do not cover the upper layers.

Contactless smart cards can be classified into three types according to the communication ranges. The ISO standards for them are ISO 10536, ISO 14443, and ISO 15693. ISO 10536 sets the standard for close-coupling smart cards, for which the communication range is about 0−1 cm. ISO 14443 sets the standard for proximity-coupling smart cards, which have a communication range of about 0−10 cm. ISO 15693 specifies vicinity-coupling smart cards, which have a communication range of about 0−1 m. The proximity-coupling and vicinity-coupling smart cards have already been implemented with some cryptography algorithms such as 128-bit AES, triple DES, and SHA-1 and challenge-response authentication mechanisms to improve system security [7].

Item management tag standards include ISO 15961, ISO 15962, ISO 15963, and ISO 18000 series [8]. ISO 15961 defines the host interrogator, tag functional commands, and other syntax features of item management. ISO 15962 defines the data syntax of item management, and ISO 15963 is "Unique Identification of RF tag and Registration Authority to manage the uniqueness." For the ISO 18000 standards series, part 1 describes the reference architecture and parameters definition; parts 2, 3, 4, 5, 6, and 7 define the parameters for air interface communications below 135 kHz, at 13.56 MHz, at 2.45 GHz, at 860 MHz, at 960 MHz, and at 433 MHz, respectively.

Standards for RFID systems for animal identification include ISO 11784, ISO 11785, and ISO 14223 [5]. ISO 11784 and ISO 11784 define the code structure and technical concepts for radiofrequency identification of animals. ISO 14223 includes three parts: air interface, code and command structure, and applications. These kinds of tags use low frequency for communication and have limited protection for animal tracking [7].

The EPC standard was created by the MIT Auto-ID, which is an association of more than 100 companies and university labs. The EPC system is currently operated by EPCglobal [8]. A typical EPC network has four parts [5]: the electronic product code, the identification system that includes RFID tags and RFID readers, the Savant middleware, and the object naming service (ONS). The first- and second-generation EPC tags cannot support strong cryptography to protect the security of the RFID systems due to the limitation of computational resources, but both of them can provide a kill command to protect the privacy of the consumer [7].

EPC tag encoding includes a Header field followed by one or more Value fields. The Header field defines the overall length and format of the Value fields. There are two kinds of EPC format: EPC 64-bit format and EPC 96-bit format. In the most recent version [9], the 64-bit format was removed from the standard. As shown in Table 18.2, both the formats include four fields: a header (8 bits), an EPC manager number (28 bits), an object class (24 bits), and a serial number (36 bits). The header and the EPC manager number are assigned by EPCglobal [8], and the object class and the serial number are assigned by EPC manager owner. The EPC header identifies the length, type, structure version, and generation of the EPC. The EPC manager number is the entity responsible for maintaining the subsequent partitions of the EPC.

TABLE 18.2 EPC Basic Format.

Header	EPC	Object Class	Serial
	Manager		Number
	Number		

The object class identifies a class of objects. Serial number identifies the instance.

RFID Applications

Recently more and more companies and organizations have begun to use RFID tags rather than traditional barcode because RFID systems have many advantages over traditional barcode systems. First, the information stored in the RFID tags can be read by RFID readers without a line of sight; whereas, barcodes can only be scanned within the line of sight. Second, the distance between a tag and a reader is longer compared with the barcode system. For example, an RFID reader can read information from a tag at a distance as long as 300 feet, whereas the read range for a barcode is typically no more than 15 feet. Third, RFID readers can scan hundreds of tags in seconds. Fourth, since today most RFID tags are produced using silicon technology, more functions can be added to them, such as large memory for more information storage and calculation ability to support various kinds of encryption and decryption algorithms, so privacy can be better protected and the tags cannot be easily cloned by attackers. In addition, the information stored in the barcode cannot be changed after being imprinted on the barcode, whereas for the RFID tags with rewritable memory the information can be updated when needed.

With these characteristics and advantages, RFID has been widely adopted and deployed in various areas. Currently, RFID can be used in passports, transportation payments, product tracking, lap scoring, animal identification, inventory systems, RFID mandates, promotion tracking, human implants, libraries, schools and universities, museums, and social retailing. These myriad applications of RFID can be classified into seven classes according to the purpose of identifying items [10]. These classes are asset management, tracking, authenticity verification, matching, process control, access control, and automated payment. Table 18.3 lists the identification purposes of various application types.

Asset management involves determining the presence of tagged items and helping manage item inventory. One possible application of asset management is electronic article surveillance (EAS). For example, every good in a supermarket is attached to an EAS tag, which will be deactivated if it is properly checked out. Then RFID readers at the supermarket exits can detect unpaid goods automatically when they pass through.

TABLE 18.3 RFID Application Purpose.

Application Type	Identification Purpose
Asset management	Determine item presence
Tracking	Determine item location
Authenticity verification	Determine item source
Matching	Ensure affiliated items are not separated
Process control	Correlate item information for decision making
Access control	Person authentication
Automated payment	Conduct financial transaction

Tracking is used to identify the location of tagged items. If the readers are fixed, a single reader can cover only one area. To effectively track the items, a group of readers is needed, together with a central system to deal with the information from different readers.

Authenticity verification methods are used to verify the source of tagged items. For example, by adding a cryptography-based digital signature in the tag, the system can prevent tag replication to make sure that a good is labeled with the source information.

Matching is used to ensure that affiliated items are not separated. Samples for matching applications include mothers and their newborn babies to match each other in the hospital and for airline passengers to match their checked luggage and so prevent theft.

Access control is used for person authentication. Buildings may use contactless RFID card systems to identify authorized people. Only those authorized people with the correct RFID card can authenticate themselves to the reader to open a door and enter a building. Using a car key with RFID tags, a car owner can open his own car automatically, another example of RFID's application to access control.

Process control involves decision making by correlating tagged item information. For example, RFID readers in different parts of an assembly line can read the information on the products, which can be used to help production managers make suitable decisions.

Automated payment is used to conduct financial transactions. The applications include payment for toll expressways and at gas stations. These applications can improve the speed of payment to hasten the processing of these transactions.

2. RFID CHALLENGES

RFID systems have been widely deployed in some areas. Perhaps this happened beyond the expectations of RFID researchers and RFID service providers. There are many limitations of the RFID technology that restrain the deployment of RFID applications, such as the lack of universal standardization of RFID in the industry and the concerns about security and privacy problems that may affect the privacy and security of individuals and organizations. The security and privacy issues pose a huge challenge for RFID applications. Here we briefly summarize some of the challenges facing RFID systems.

Counterfeiting

As described earlier in the chapter, RFID tags can be classified into three categories based on the equipped computation power: basic tags, symmetric-key tags, and public-key tags. Symmetric-key and public-key tags can implement cryptography protocols for authentication with private key, and public keys, respectively. Basic tags are not capable of performing cryptography computation. Although they lack the capability to perform cryptography computation, they are most widely used for applications such as supply chain management and travel systems. With the widespread application of fully writable or even reprogrammable basic tags, counterfeiters can easily forge basic tags in real-world applications, and these counterfeit tags can be used in multiple places at the same time, which can cause confusion.

The counterfeiting of tags can be categorized into two areas based on the technique used for tampering with tag data: modifying tag data and adding data to a blank tag. In real-world applications, we face counterfeit threats such as the following [7]:

- The attacker can modify valid tags to make them invalid or modify invalid tags to make them valid.
- The attacker can modify a high-priced object's tag as a low-priced object or modify a low-priced object's tag as a high-priced object.
- The attacker can modify an object's tag to be the same as the tags attached to other objects.
- The attacker can create an additional tag for personal reasons by reading the data from an authorized tag and adding this data to a blank tag in real-world applications, such as in a passport or a shipment of goods.

Sniffing

Another main issue of concern in deploying RFID systems is the sniffing problem. It occurs when third parties use a malicious and unauthorized RFID reader to read the information on RFID tags within their transmission range. Unfortunately, most RFID tags are indiscriminate in their responses to reading requests transmitted by RFID readers and do not have access control functions to provide any protection against an unauthorized reader. Once an RFID tag enters a sufficiently powered reader's field, it receives the reader's requests via radio frequency. As long as the request is well formed, the tag will reply to the request with the corresponding information on the tag. Then the holder of the unauthenticated reader may use this information for other purposes.

Tracking

With multiple RFID readers integrated into one system, the movements of objects can be tracked by fixed RFID readers [11]. For example, once a specific tag can be associated with a particular person or object, when the tag enters a reader's field the reader can obtain the specific identifier of the tag, and the presence of the tag within the range of a specific reader implies specific location information related to the attached person or object. With location information coming from multiple RFID readers, an attacker can follow movements of people or objects. Tracking can also be performed without decrypting the encrypted messages coming from RFID readers [5]. Generally, the more messages the attacker describes, the more location or privacy information can be obtained from the messages.

One way to track is to generate maps of RFID tags with mobile robots [12]. A sensor model is introduced to compute the likelihood of tag detections, given the relative pose of the tag with respect to the robot. In this model a highly accurate FastSLAM algorithm is used to learn the geometrical structure of the environment around the robots, which are equipped with a laser range scanner; then it uses the recursive Bayesian filtering scheme to estimate the posterior locations of the RFID tags, which can be used to localize robots and people in the environment with the geometrical structure of the environment learned by the FastSLAM algorithm.

There is another method to detect the motion of passive RFID tags that are within a detecting antenna's field. Response rate at the reader is used to study the impact of four cases of tag movements that can provide prompt and accurate detection and the influence of the environment. The idea of multiple tags/readers is introduced to improve performance. The movement-detection algorithms can be improved and integrated into the RFID monitoring system to localize the position of the tags. The method does not require any modification of communication protocols nor the addition of hardware. In real-world applications, there exists the following tracking threat: The attacker can track the potential victim by monitoring the movement of

the person and performing some illegal actions against the potential victim [13].

Now, let's take a very brief look at denial of service threats. Availability enables a Web services application to detect a Denial of Service (DoS) attack, to continue operation as long as possible, and then to gracefully recover and resume operations after a DoS attack. There is a need for techniques to replicate data and services to ensure continuity of operations in the event of a fault or threat (see checklist: "An Agenda For Action When Thwarting DoS Threats"). There is also a need for management and monitoring solutions to provide service performance and availability monitoring to meet certain service level objectives.

Other Issues

Besides the four basic types of attack (counterfeiting, sniffing, tracking, and denial of service) in real-world applications, there also exists some other threats to RFID systems.

Spoofing

Spoofing attacks take place when an attacker successfully poses as an authorized user of a system [13]. Spoofing attacks are different from counterfeiting and sniffing attacks, though they are all falsification types of attack. Counterfeiting takes place when an attacker forges the RFID tags that can be scanned by authorized readers. Sniffing takes place when an attacker forges authorized readers that can scan the authorized tags to obtain useful information. But the forging object of spoofing is an authorized user of a system. There exist the following spoofing threats in real-world applications [13]:

- *The attacker can pose as an authorized EPC global Information Service Object Naming Service (ONS) user*. If the attacker successfully poses as an authorized ONS user, he can send queries to the ONS to gather EPC numbers. Then, from the EPC numbers, the attacker may easily obtain the location, identification, or other privacy information.
- *The attacker can pose as an authorized database user in an RFID system*. The database stores the complete

An Agenda for Action when Thwarting DoS Threats

Denial of service (DoS) takes place when RFID readers or back-end servers cannot provide excepted services. DoS attacks are easy to accomplish and difficult to guard against [13]. The following are nine DoS threats (check all tasks completed):

_____**1.** *Killing tags to make them disabled to disrupt readers' normal operations.* EPCglobal had proposed that a tag have a "kill" command to destroy it and protect consumer privacy. If an attacker knows the password of a tag, it can "kill" the tag easily in real-world applications. Now Class-0, Class-1 Generation-1, and Class-1 Generation-2 tags are all equipped with the kill command.

_____**2.** Carry a blocker tag that can disrupt the communication between an RFID reader and RFID tags. *A blocker tag is a cheap, passive RFID device that can simulate many basic RFID tags at one time and render specific zones private or public. An RFID reader can only communicate with a single RFID tag at any specific time. If more than one tag responds to a request coming from the reader at the same time, "collision" happens. In this case, the reader cannot receive the information sent by the tags, which makes the system unavailable to authorized uses.*

_____**3.** Carry a special absorbent tag that can be tuned to the same radio frequencies used by legitimate tags. *The absorbent tag can absorb the energy or power generated by radiofrequency signals sent by the reader, and the resulting reduction in the reader's energy may make the reader unavailable to communicate with other tags.*

_____**4.** *Remove, physically destroy, or erase the information on tags attached to or embedded in objects.* The reader will not communicate with the dilapidated tags in a normal way.

_____**5.** *Shield the RFID tags from scrutiny using a Faraday cage.* A Faraday cage is a container made of a metal enclosure that can prevent reading radio signals from the readers [14].

_____**6.** *Carry a device that can actively broadcast more powerful return radio signals or noises than the signals responded to by the tags so as to block or disrupt the communication of any nearby RFID readers and make the system unavailable to authorized users.* The power of the broadcast is so high that it could cause severe blockage or disruption of all nearby RFID systems, even those in legitimate applications where privacy is not a concern [14].

_____**7.** *Perform a traditional Internet DoS attack and prevent the back-end servers from gathering EPC numbers from the readers.* The servers do not receive enough information from the readers and cannot provide the additional services from the server.

_____**8.** *Perform a traditional Internet DoS attack against the object-naming service (ONS).* This can deny the service.

_____**9.** *Send URL queries to a database and make the database busy with these queries.* The database may then deny access to authorized users.

information from the objects, such as manufacturer, product name, read time, read location, and other privacy information. If the attacker successfully poses as an authorized database user and an authorized user of ONS, he can send queries to the ONS for obtaining the EPC number of one object, then get the complete information on the object by mapping the EPC number to the information stored in the database.

- *The attacker can also pose as an ONS server*. If the attacker's pose is successful, he can easily use the ONS server to gather EPC numbers, respond to invalid requests, deny normal service, and even change the data or write malicious data to the system.

Repudiation

Repudiation takes place when a user denies doing an action or no proof exists to prove that the action has been implemented [13]. There are two kinds of repudiation threats:

- The sender or the receiver denies performing the send and receive actions. A non-repudiation protocol can be used to resolve this problem.
- The owner of the EPC number or the back-end server denies that it has the information from the objects to which the tags are attached.

Insert Attacks

Insert attacks take place when an attacker inserts some system commands to the RFID system where data is normally expected [15]. In real-world applications, there exists the following attack: A system command rather than valid data is carried by a tag in its data storage memory.

Replay Attacks

Replay attacks take place when an attacker intercepts the communication signals between an RFID reader and an RFID tag and records the tag's response. Then the RFID tag's response can be reused if the attacker detects that the reader sends requests to the other tags for querying [16]. There exist the following two threats:

- The attacker can record the communications between proximity cards and a building access reader and play it back to access the building.
- The attacker can record the response that an RFID card in a car gives to an automated highway toll collection system, and the response can be used when the car of the attacker wants to pass the automated toll station.

Physical Attacks

Physical attacks are very strong attacks that physically obtain tags and have unauthorized physical operations on the tags. But it is fortunate that physical attacks cannot be implemented in public or on a widespread scale, except for Transient Electromagnetic Pulse Emanation Standard (TEMPEST) attacks. There exist the following physical attacks [1,17]:

- *Probe attacks*. The attacker can use a probe directly attached to the circuit to obtain or change the information on tags.
- *Material removal*. The attacker can use a knife or other tools to remove the tags attached to objects.
- *Energy attacks*. The attacks can be either of the contact or contactless variety. It is required that contactless energy attacks be close enough to the system.
- *Radiation imprinting*. The attacker can use an X-ray band or other radial bands to destroy the data unit of a tag.
- *Circuit disruption*. The attacker can use strong electromagnetic interference to disrupt tag circuits.
- *Clock glitch*. The attacker can lengthen or shorten the clock pulses to a clocked circuit and destroy normal operations.

Viruses

Viruses are old attacks that threaten the security of all information systems, including RFID systems. RFID viruses always target the back-end database in the server, perhaps destroying and revealing the data or information stored in the database. There exist the following virus threats:

- An RFID virus destroys and reveals the data or information stored in the database.
- An RFID virus disturbs or even stops the normal services provided by the server.
- An RFID virus threatens the security of the communications between RFID readers and RFID tags or between back-end database and RFID readers.

Social Issues

Due to the security challenges in RFID, many people do not trust RFID technologies and fear that they could allow attackers to purloin their privacy information.

Weis [16] presents two main arguments. These arguments make some people choose not to rely on RFID technology and regard RFID tags as the "mark of the beast." However, security issues cannot prevent the success of RFID technology.

The first argument is that RFID tags are regarded as the best replacement for current credit cards and all other

ways of paying for goods and services. But RFID tags can also serve as identification. The replacement of current ways of paying by RFID tag requires that people accept RFID tags instead of credit cards, and they cannot sell or buy anything without RFID tags.

There is a second argument [16]: "Since RFID tags are also used as identification, they should be implanted to avoid losing the ID or switching it with someone. Current research has shown that the ideal location for the implant is indeed the forehead or the hand, since they are easy to access and unlike most other body parts they do not contain much fluid, which interferes with the reading of the chip."

Comparison of All Challenges

Previously in this chapter we introduced some of the challenges that RFID systems are facing. Every challenge or attack can have a different method or attack goal, and the consequences of the RFID system after an attack may also be different. In this part of the chapter, we briefly analyze the challenges according to attack methods, attack goals, and the consequences of RFID systems after attacks (see Table 18.4).

The first four challenges are the four basic challenges in RFID systems that correspond to the four basic use cases. *Counterfeiting* happens when counterfeiters forge RFID tags by copying the information from a valid tag or adding some well-formed format information to a new tag in the RFID system. *Sniffing* happens when an unauthorized reader reads the information from a tag, and the information may be utilized by attackers. *Tracking* happens when an attacker who holds some readers unlawfully monitors the movements of objects attached by an RFID tag that can be read by those readers. *Denial of service* happens when the components of RFID systems deny the RFID service.

The last seven challenges or attacks can always happen in RFID systems (see Table 18.4). *Spoofing* happens when an attacker poses as an authorized user of an RFID system on which the attacker can perform invalid operations. *Repudiation* happens when a user or component of an RFID system denies the action it performed and there is no proof that the user did perform the action. *Insert attacks* happen when an attacker inserts some invalid system commands into the tags and some operations may be implemented by the invalid command. *Replay attacks* happen when an attacker intercepts the response of the tag and reuses the response for another communication. *Physical attacks* happen when an attacker does some physical operations on RFID tags and these attacks disrupt communications between the RFID readers and tags. A *virus* is the security challenge of all information systems; it can disrupt the operations of RFID systems or reveal the information in those systems. *Social issues* involve users' psychological attitudes that can influence the users' adoption of RFID technologies for real-world applications.

TABLE 18.4 Comparison of all Challenges or Attacks in RFID Systems.

Challenge or Attack	Attack Method	Attack Goal	Direct Consequence
Counterfeiting	Forge tags	Tag	Invalid tags
Sniffing	Forge readers	Reader	Reveals information
Tracking	Monitor the movement of objects	Objects of an RFID system	Tracks the movement of object
Denial of service	RF jamming, kill normal command, physical destroy, and so on	Reader, back-end database or server	Denies normal services
Spoofing	Pose as an authorized user	User	Invalid operations by invalid user
Repudiation	Deny action or no proof that the action was implemented	Tag, reader, back-end database or server	Deniable actions
Insert attacks	Insert invalid command	Tag	Invalid operations by invalid commands
Replay attacks	Reuse the response of tags	Communication between RFID tags and readers	Invalid identification
Physical attacks	Physical operations on tag	Tag	Disrupts or destroys communication between RFID tags and readers
Virus	Insert invalid data	Back-end database or server	Destroys the data or service of system
Social issues	Social attitude	Psychology of potential user	Restricts the widespread application

3. RFID PROTECTIONS

According to their computational power, RFID tags can be classified into three categories: basic tags, symmetric-key tags, and public-key tags. In the next part of the chapter, we introduce some protection approaches for these three kinds of RFID tags.

Basic RFID System

Prices have been one of the biggest factors to be considered when we're making decisions on RFID deployments. Basic tags are available for the cheapest price, compared with symmetric-key tags and public-key tags. Due to the limited computation resources built into a basic tag, basic tags are not capable of performing cryptography computations. This imposes a huge challenge to implement protections on basic tags; cryptography has been one of the most important and effective methods to implement protection mechanisms. Recently several approaches have been proposed to tackle this issue.

Most of the approaches to security protection for basic tags focus on protecting consumer privacy. A usual method is by tag killing, proposed by EPCglobal. In this approach, when the reader wants to kill a tag, it sends a kill message to the tag to permanently deactivate it. Together with the kill message, a 32-bit tag-specific PIN code is also sent to the object tag, to avoid killing other tags. On receiving this kill message, a tag will deactivate itself, after which the tag will become inoperative. Generally, tags are killed when the tagged items are checked out in shops or supermarkets. This is very similar to removing the tags from the tagged items when they are purchased. It is an efficient method of protecting the privacy of consumers, since a killed tag can no longer send out information.

The disadvantage of this approach is that it will reduce the post-purchase benefits of RFID tags. In some cases, RFID tags need to be operative only temporarily. For example, RFID tags used in libraries and museums for tagging books and other items need to work at all times and should not be killed or be removed from the tagged items. In these cases, instead of being killed or removed, tags can be made temporarily inactive. When a tag needs to be reawoken, an RFID reader can send a wake message to the tag with a 32-bit tag-specific PIN code, which is sent to avoid waking up other tags. This also results in the management of PIN codes for tags, which brings some inconvenience.

Another approach to protecting privacy is tag relabeling, which was first proposed by Sarma et al [18]. In this scheme, to protect consumers' privacy, identifiers of RFID tags are effaced when tagged items are checked out, but the information on the tags will be kept for later use. Inoue and Yasuuran [19] proposed that consumers can store the identifiers of the tags and give each tag a new identifier. When needed, people can reactivate the tags with the new identifiers. This approach allows users to manage tagged items throughout the items' life cycle. A third approach is to allocate each tag a new random number at each checkout; thus attackers cannot rely on the identifiers to collect information about customers [20]. This method does not solve the problem of tracking [20]. To prevent tracking, random numbers need to be refreshed frequently, which will increase the burden on consumers. Juels proposed a system called the *minimalist system* [21], in which every tag has a list of pseudonyms, and for every reader query, the tag will respond with a different pseudonym from the list and return to the beginning of the list when this list is exhausted. It is assumed that only authorized readers know all these tag pseudonyms. Unauthorized readers that do not know these pseudonyms cannot identify the tags correctly. To prevent unauthorized readers getting the pseudonyms list by frequent query, the tags will response to an RFID reader's request with a relatively low rate, which is called *pseudonym throttling*. Pseudonym throttling is useful, but it cannot provide a high level of privacy for consumers, because with the tag's small memory, the number of pseudonyms in the list is limited. To tackle this problem, the protocol allows an authorized RFID reader to refresh a tag's pseudonyms list.

Juels and Pappu [22] proposed to protect consumers' privacy by using tagged banknotes. The proposed scheme used public-key cryptography to protect the serial numbers of tagged banknotes. The serial number of a tagged banknote is encrypted using a public key to generate a ciphertext, which is saved in the memory of the tag. On receiving a request of the serial number, the tag will respond with this ciphertext. Only law enforcement agencies know the related private key and can decrypt this ciphertext to recover the banknote's serial number. To prevent tracking of banknotes, the ciphertext will be reencrypted periodically. To avoid the ciphertext of a banknote being reencrypted by an attacker, the tagged banknote can use an optical write – access key. A reader that wants to reencrypt this ciphertext needs to scan the write – access key first. In this system only one key pair, a public key and a private key, is used. But this is not enough for the general RFID system. Using multiple key pairs will impair the privacy of RFID systems, since if the reader wants to reencrypt the ciphertext, it needs to know the corresponding public key of this tag.

So, a universal reencryption algorithm has been introduced [23]. In this approach, an RFID reader can reencrypt the ciphertext without knowing the corresponding public key of a tag. The disadvantage of this approach is that attackers can substitute the ciphertext with a new

ciphertext, so the integrity of the ciphertext cannot be protected. By signing the ciphertext with a digital signature, this problem can be solved [24], since only the authenticated reader can access the ciphertext.

Floerkemeier (et al.) [25] introduced another approach to protect consumer privacy by using a specially designed protocol. In their approach, they first designed the communication protocol between RFID tags and RFID readers. This protocol requires an RFID reader to provide information about the purpose and the collection type for the query. In addition, a privacy-enforcing device called a *watchdog tag* is used in the system. This watchdog tag is a kind of sophisticated RFID tag that is equipped with a battery, a small screen, and a long-range communication channel. A watchdog tag can be integrated into a PDA or a cell phone and can decode the messages from an RFID reader and display them on the screen for the user to read. With a watchdog tag, a user can know not only the information from the RFID readers in the vicinity of the tag but also the ID, the query purpose, and the collection type of the requests sent by the RFID readers. With this information, the user is able to identify the unwanted communications between tags and an RFID reader, making this method useful for users to avoid the reader ID spoofing attack.

Rieback, Crispo, and Tanebaum [26] proposed another privacy-enforcing device called RFID Guardian, which is also a battery-powered RFID tag that can be integrated into a PDA or a cell phone to protect user privacy. RFID Guardian is actually a user privacy protection platform in RFID systems. It can also work as an RFID reader to request information from RFID tags, or it can work like a tag to communicate with a reader. RFID Guardian has four different security properties: auditing, key management, access control, and authentication. It can audit RFID readers in its vicinity and record information about the RFID readers, such as commands, related parameters, and data, and provide these kinds of information to the user. Using this information, the user can sufficiently identify illegal scanning. In some cases, a user might not know or could forget the tags in his vicinity. With the help of RFID Guardian, the user can detect all the tags within radio range. Then the user can deactivate the tags according to his choice.

For RFID tags that use cryptography methods to provide security, one important issue is key management. RFID Guardian can perform two-way RFID communications and can generate random values. These features are very useful for key exchange and key refresh. Using the features of coordination of security primitives, context awareness, and tag-reader mediation, RFID Guardian can provide access control for RFID systems [26]. Also, using two-way RFID communication and standard challenge-response algorithms, RFID Guardian can provide off-tag authentication for RFID readers.

Another approach for privacy protecting is proposed by Juels, Rivest, and Szydlo [14]. In this approach, a cheap, passive RFID tag is used as the blocker tag. Since this blocker tag can simulate many RFID tags at the same time, it is very difficult for an RFID reader to identify the real tag carried by the user. The blocker tag can both simulate all the possible RFID tags and simulate only a select set of the tags, making it convenient for the user to manage the RFID tags. For example, the user can tell the blocker tag to block only the tags that belong to a certain company. Another advantage of this approach is that if the user wants to reuse these RFID tags, unlike the "killed" tags that need to be activated by the user, the user need only remove the blocker tag. Since the blocker tag can shield the serial numbers of the tags from being read by RFID readers, it can also be used by attackers to disrupt proper operation of an RFID system. A thief can also use the blocker tag to shield the tags attached to the commodities in shops and take them out without being detected.

RFID System Using Symmetric-Key Cryptography

Symmetric-key cryptography, also called *secret-key cryptography* or *single-key cryptography*, uses a single key to perform both encryption and decryption. Due to the limited amount of resources available on an RFID chip, most available symmetric-key cryptographs are too costly to be implemented on an RFID chip. For example, a typical implementation of Advanced Encryption Standard (AES) needs about 2000−3000 gates. This is not appropriate for low-cost RFID tags. It is only possible to implement AES in high-end RFID tags. A successful case of implementing a 128-bit AES on high-end RFID tags has been reported [27].

Using the Symmetric Key to Provide Authentication and Privacy

Symmetric-key cryptography can be applied to prevent tag cloning in RFID systems using a challenge and response protocol. For example, if a tag shares a secret key K with a reader and the tag wants to authenticate itself to the reader, it will first send its identity to the reader. The reader will then generate a nonce N and send it to the tag. The tag will use this nonce and the secret K to generate a hash code $H = h(K,N)$ and send this hash code to the reader. The reader can also generate a hash code $H' = h(K,N)$ and compare these two codes to verify this tag. Using this scheme, it is difficult for an attacker to clone the tags without knowing the secret keys.

Different kinds of symmetric-key cryptography protocol-based RFID tags have been used recently in

daily life. For example, an RFID device that uses this symmetric-key challenge-response protocol, called a digital signature transponder, has been introduced by Texas Instruments. This transponder can be built into cars to prevent car theft and can be implemented into wireless payment devices used in filling stations.

One issue of RFID systems that use symmetric-key cryptography is key management. To authenticate itself to an RFID reader, each tag in the system should share a different secret key with the reader, and the reader needs to keep all the keys of these tags. When a tag wants to authenticate itself to an RFID reader, the reader needs to know the secret key shared between them. If the reader does not know the identification of the tag in advance, it cannot determine which key can be used to authenticate this tag. If the tag sends its identification to the reader before the authentication for the reader to search the secret key, the privacy of the tag cannot be protected, since other readers can also obtain the identification of this tag.

To tackle this problem, one simple method is *key searching*. The reader will search all the secret keys in its memory to find the right key for the tag before authentication. There are some protocols proposed for the key search for RFID tags. One general kind of key search scheme [11] has been proposed. In this approach, the tag first generates a random nonce N and hashes this N using its secret key K to generate the hash code. Then it sends both this hash code and N to the reader. Using this nonce N, the reader will generate the hash code with all the secret keys and compare them with the received hash code from the tag. If there is a match, it means it found the right key. In this scheme, since the nonce N is generated randomly every time, the privacy of the tag can be protected.

The problem with this approach is that if there are a large number of tags, the key searching will be very costly. To reduce the cost of the key searching, a modification of this scheme was proposed [28]; in [12], in this approach, a scheme called *tree of secret* is used. Every tag is assigned to a leaf in the tree, and every node in the tree has its secret key. This way the key search cost for each tag can be reduced, but it will add some overlap to the sets of keys for each tag.

Another approach to reduce the cost of key searching is for the RFID tags and RFID reader to keep synchronization with each other. In this kind of approach, every tag will maintain a counter for the reader query times. For each reader's query, the tag should respond with a different value. The reader will also maintain counters for all the tags' responses and maintain a table of all the possible response values. Then, if the reader and tags can keep synchronization, the reader can know the approximate current counter number of the tags. When the reader receives a response from a tag, it can search the table and quickly identify this tag.

Other Symmetric-Key Cryptography-based Approaches

In addition to the basic symmetric-key challenge-response protocol, some symmetric-key cryptography-based approaches have been proposed recently to protect the security and privacy of RFID systems.

One approach is called YA-TRAP: Yet Another T rivial RFID Authentication Protocol, proposed by Tsudik [29]. In this approach, a technique for the inexpensive untraceable identification of RFID tags is introduced. Here *untraceable* means it is computationally difficult to gather the information about the identity of RFID tags from the interaction with them. In YA-TRAP, for the purpose of authentication, only minimal communication between the reader and tags is needed, and the computational burden on the back-end server is very small.

The back-end server in the system is assumed to be secure and maintains all tag information. Each tag should be initialized with three values: K_i, T_0, and T_{max}. K_i is both the identifier and the cryptographic key for this tag. The size of K_i depends on the number of tags and the secure authentication requirement; in practice, 160 bits is enough. T_0 is the initial timestamp of this tag. The value of T_0 of each tag does not need to vary. This means that a group of tags can have the same T_0. T_{max} is the maximum value of T_0, and a group of tags can also have the same T_{max} value. In addition, each tag has a seeded pseudorandom number generator.

YA-TRAP works as follows: First, each tag should store a timestamp T_t in its memory. When an RFID reader wants to interrogate a RFID tag, it will send the current timestamp T_r to this tag. Receiving T_r, the tag will compare T_r with the timestamp value it stores and with T_{max}. If $T_r < T_t$ or $T_r > T_{max}$, this tag will respond to the reader with a random value generated by the seeded pseudo random number generator. Otherwise, the tag will replace T_t with T_r and calculate $H_r = HMACK_i(T_t)$, and then send H_r to the reader. Then the reader will send T_r and H_r to the back-end server. The server will look up its database to find whether this tag is a valid tag. If it's not, the server will send a tag-error message to the reader. If this is a valid tag, the server will send the meta-ID of this tag or the valid message to the reader, according to different application requirements. Since the purpose of this protocol is to minimize the interaction between the reader and tags and minimize the computation burden of the back-end server, it has some vulnerability. One of them is that the adversary can launch a DoS attack to the tag. For example, the attack can send a timestamp $t < T_{max}$, but this t is wildly inaccurate with the current time. In this

case, the tag will update its timestamp with the wrong time and the legal reader cannot get access to this tag.

In Ref. [16], another approach called *deterministic hash locks* [11] was proposed. In this scheme, the security of RFID systems is based on the one-way hash function. During initialization, every tag in the system will be given a meta-ID, which is the hash code of a random key. This meta-ID will be stored in the tag's memory. Both the meta-ID and the random key are also stored in the back-end server. After initialization, all the tags will enter the locked state. When they stay in the locked state, tags will respond only with the meta-ID when interrogated by an RFID reader. When a legitimate reader wants to unlock a tag, as shown in Figure 18.2, it will first send a request to the tag. After receiving the meta-ID from the tag, the reader will send this meta-ID to the back-end server. The back-end server will search in its database using this meta-ID to get the random key. Then it will send this key to the reader, and the reader will send it to the tag. Using this random key, the tag will hash this key and compare the hash code with its meta-ID. The tag will unlock itself and send its actual identification to the reader if these two values match. Then the tag will return to the locked state to prevent hijacking of illegal readers. Since the illegal reader cannot contact the back-end server to get the random key, it cannot get the actual identification of the tag.

One problem with deterministic hash locks is that when the tag is queried, it will respond with its meta-ID. Since the meta-ID of the tag is a static one and cannot change, the tag can be tracked easily. To solve this problem, Weis, Sarma, Rivest, and Engels proposed the Randomized Hash Locks protocol to prevent tracking of the tag. In this protocol, each tag is equipped with not only the one-way hash function but also a random number generator. When the tag is requested by a reader, it will use the random number generator to generate a random number and will hash this random number together with its identification. The tag will respond with this hash code and the random number to the reader. After receiving this response from the tag, the reader will get all identifications of the tags from the back-end server. Using these identifications, the reader will perform brute-force search by hashing the identification of each tag together with the random number and compare the hash code. If there is a

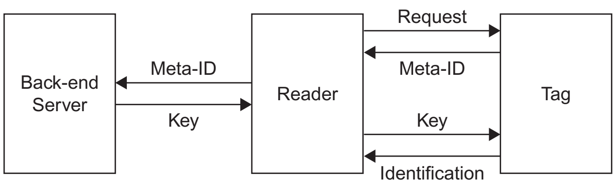

FIGURE 18.2 Tag unlock.

match, the reader can know the identification of the tag. In this approach, the tag response to the reader is not dependent on the request of the reader, which means that the tag is vulnerable to replay attack. To avoid this, Juels and Weis proposed a protocol called Improved Randomized Hash-Locks [30].

RFID System using Public-Key Cryptography

Symmetric-key cryptography can provide security for RFID systems, but it is more suitable to be implemented in a closed environment. If the shared secret keys between them are leaked, it will impose a big problem for the security of RFID systems. Public-key cryptography is more suitable for open systems, since both RFID readers and tags can use their public keys to protect the security of RFID systems. In addition, using public-key cryptography can not only prevent leakage of any information to the eavesdropper attack during communication between reader and tags, it also can provide digital signatures for both the readers and tags for authentication. In the public-key cryptography system, an RFID reader does not need to keep all the secret keys for each tag and does not need to search the appropriate key for each tag as it does in a symmetric-key cryptography system. This will reduce the system burden for key management. Although public-key cryptography has some advantages over symmetric-key cryptography, it is commonly accepted that public-key cryptography is computationally more expensive than symmetric-key cryptography. Because of the limitations of memory and computational power of the ordinary RFID tags, it is difficult for the public-key cryptography to be implemented in RFID systems. In recent years, some research shows that some kinds of public key-based cryptographies such as elliptic curve cryptography and hyperelliptic curve cryptography are feasible to be implemented in high-end RFID tags [31].

Authentication with Public-Key Cryptography

Basically, there are two different kinds of RFID tag authentication methods that use public-key cryptography: one is online authentication and the other is offline authentication [32].

For the authentication of RFID tags in an online situation, the reader is connected with a database server. The database server stores a large number of challenge-response pairs for each tag, making it difficult for the attacker to test all the challenge-response pairs during a limited time period. During the challenge-response pairs enrollment phase, the physical uncloneable function part of RFID systems will be challenged by a Certification Authority with a variety of challenges, and accordingly it will generate responses for these challenges. The physical

uncloneable function is embodied in a physical object and can give responses to the given challenges [31]. Then these generated challenge-response pairs will be stored in the database server.

In the authentication phase, when a reader wants to authenticate a tag, first the reader will send a request to the tag for its identification. After getting the ID of the tag, the reader will search the database server to get a challenge-response pair for this ID and send the challenge to the tag. After receiving the challenge from the reader, the tag will challenge its physical uncloneable function to get a response for this challenge and then send this response to the reader. The reader will compare this received response with the response stored in the database server. If the difference between these two responses is less than a certain predetermined threshold, the tag can pass the authentication. Then the database server will remove this challenge-response pair for this ID.

One paper [31] details how the authentication of RFID tags works in an offline situation using public key cryptography. To provide offline authentication for the tags, a PUF-Certificate-Identify-based identification scheme is proposed. In this method, a standard identification scheme and a standard signature scheme are used. Then the security of RFID systems depends on the security of the PUF, the standard identification scheme, and the standard signature scheme. For the standard identification scheme, an elliptic curve discrete log based on Okamoto's Identification protocol [33] is used. This elliptic curve discrete log protocol is feasible to be implemented in the RFID tags.

Identity-Based Cryptography Used in the RFID Networks

An identity-based cryptographic scheme is a kind of public-key-based approach that was first proposed by Shamir [34] in 1984. To use identity-based cryptography in RFID systems, since both the RFID tags and the reader have their identities, it is convenient for them to use their own identities to generate their public keys.

An RFID system based on identity-based cryptography should be set up with the help of a PKG. When the reader and tags enter the system, each of them is allocated a unique identity stored in their memory. The process of key generation and distribution in the RFID system that uses identity-based cryptography is shown in Figure 18.3 and is outlined here:

1. PKG generates a "master" public key PU_{pkg} and a related "master" private key PR_{pkg} and saves them in its memory.
2. The RFID reader authenticates itself to the PKG with its identity ID_{re}.

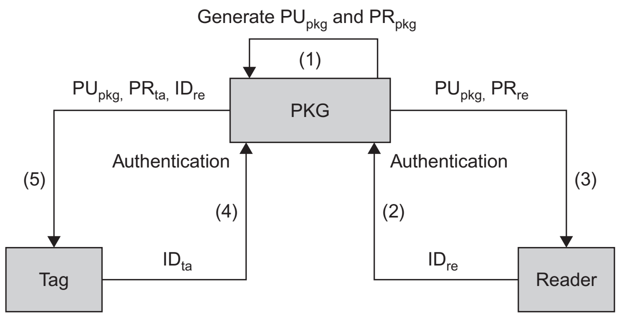

FIGURE 18.3 Key generation and distribution.

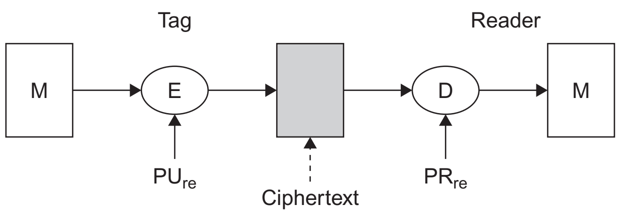

FIGURE 18.4 Message encryption.

3. If the reader can pass the authentication, PKG generates a unique private key PR_{re} for the reader and sends this private key together with PU_{pkg} to reader.
4. When an RFID tag enters the system, it authenticates itself to the PKG with its identity ID_{ta}.
5. If the tag can pass the authentication, PKG generates a unique private key PR_{ta} for the tag and sends PR_{ta} together with PU_{pkg} and the identity of the reader ID_{re} to the tag.

After this process, the reader can know its private key PR_{re} and can use PU_{pkg} and its identity to generate its public key. Every tag entered into the system can know its own private key and can generate a public key of its own and a public key of the reader.

If an RFID tag is required to transmit messages to the reader in security, since the tag can generate the reader's public key PU_{re}, it can use this key PU_{re} to encrypt the message and transmit this encrypted message to the reader. As shown in Figure 18.4, after receiving the message from the tag, the reader can use its private key $PR_{re}$to decrypt the message. Since only the reader can know its private key PR_{re}, the security of the message can be protected.

Figure 18.5 illustrates the scheme for the reader to create its digital signature and verify it. First, the reader will use the message and the hash function to generate a hash code, and then it uses its private key PR_{re} to encrypt this hash code to generate the digital signature and attach it to the original message and send both the digital signature and message to the tag. After receiving them, the

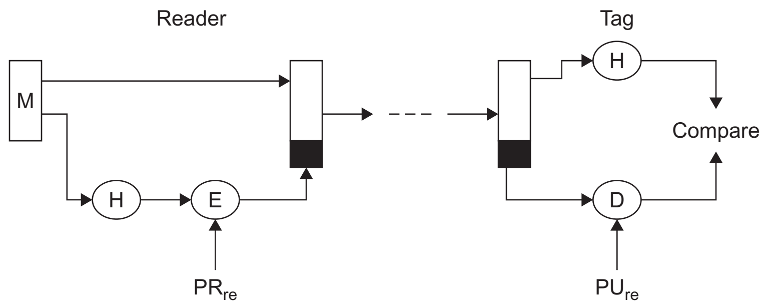

FIGURE 18.5 A digital signature from a reader.

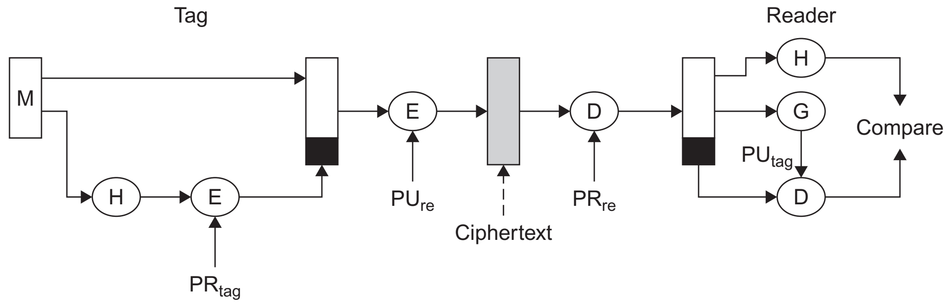

FIGURE 18.6 A digital signature from a tag.

RFID tag can use the public key of the reader PU_{re} to decrypt the digital signature to recover the hash code. By comparing this hash code with the hash code generated from the message, the RFID tag can verify the digital signature.

Figure 18.6 illustrates the scheme for the RFID tag to create its digital signature and verify it. In RFID systems, the reader cannot know the identity of the tag before reading it from the tag. The reader cannot generate the public key of the tag, so the general protocol used in identity-based networks cannot be used here. In our approach, first, the tag will use its identity and its private key $PR_{ta}$to generate a digital signature. When the tag needs to authenticate itself to the reader, it will add this digital signature to its identity, encrypt it with the public key of the reader PU_{re}, and send to the reader; only the reader can decrypt this ciphertext and get the identity of the tag and the digital signature. Using the tag identity, the reader can generate the tag's public key PU_{ta}. Then the reader can use this public key to verify the digital signature.

As mentioned, the most important problem for the symmetric-key approach in RFID systems is the key management. The RFID tags need a great deal of memory to store all the secret keys related with each tag in the system for message decryption. Also, if the RFID reader receives a message from a tag, it cannot know which tag this message is from and therefore cannot know which key it can use to decrypt the message. The reader needs to search all the keys until it finds the right one. In RFID systems using identity-based cryptography, every tag can use the public key of the reader to generate the ciphertext that can be decrypted using the reader's private key, so the reader does not need to know the key of the tags; all it needs to keep is its own private key.

In some RFID applications such as epassports and visas, tag authentication is required. However, the symmetric-key approach cannot provide digital signatures for RFID tags to authenticate them to RFID readers. By using an identity-based scheme, the tags can generate digital signatures using their private keys and store them in the tags. When they need to authenticate themselves to RFID readers, they can transmit these digital signatures to the reader, and the reader can verify them using the tags' public keys.

In identity-based cryptography RFID systems, since the identity of the tags and reader can be used to generate public keys, the PKG does not need to keep the key directory, so it can reduce the resource requirements. Another advantage of using identity-based cryptography in RFID systems is that the reader does not need to know the public keys of the tags in advance. If the reader wants to verify the digital signature of an RFID tag, it can read the identity of the tag and use the public key generated from the identity to verify the digital signature.

An inherent weakness of identity-based cryptography is the key escrow problem. But in RFID systems that use identity-based cryptography, because all the devices can be within one company or organization, the PKG can be highly trusted and protected, and the chance of key escrow can be reduced.

Another problem of identity-based cryptography is revocation. For example, people always use their public information such as their names or home addresses to generate their public key. If a person's private keys are compromised by an attacker, since public information cannot be changed easily, this will make it difficult to regenerate new public keys. In contrast, in RFID systems the identity of the tag is used to generate the public key. If the private key of one tag has been compromised, the system can allocate a new identity to the tag and use this new identity to effortlessly create a new private key to the tag.

4. SUMMARY

Like any information technology (IT), radio frequency identification (RFID) presents security and privacy risks that must be carefully mitigated through management, operational, and technical controls in order to realize the numerous benefits the technology has to offer. When practitioners adhere to sound security engineering principles, RFID technology can help a wide range of organizations and individuals realize substantial productivity gains and efficiencies. These organizations and individuals include hospitals and patients, retailers and customers, and manufacturers and distributors throughout the supply chain. This chapter provided detailed coverage of RFID technology, the associated security and privacy risks, and recommended practices that will enable organizations to realize productivity improvements while safeguarding sensitive information and protecting the privacy of individuals. While RFID security is a rapidly evolving field with a number of promising innovations expected in the coming years, these guidelines focus on controls that are commercially available today.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Data carriers attached to objects are called RFID tags.
2. True or False? Currently, as different frequencies are used for RFID systems in various countries and many standards are adopted for different kinds of application, there is an agreement on a universal standard that's accepted by all parties.
3. True or False? Recently more and more companies and organizations have begun to use RFID tags rather than traditional barcode because RFID systems have many advantages over traditional barcode systems.
4. True or False? RFID tags can be classified into three categories based on the equipped computation power: basic tags, symmetric-key tags, and public-key tags.
5. True or False? Another main issue of concern in deploying RFID systems is the sniffing problem.

Multiple Choice

1. Besides the four basic types of attack (counterfeiting, sniffing, tracking, and denial of service) in real-world applications, there also exists some other threats to RFID systems, like:
   - **A.** Spoofing
   - **B.** Temporal Key Integrity Protocols (TKIP)
   - **C.** Application Program Interfaces
   - **D.** Network Areas
   - **E.** Extensible Authentication Protocol (EAP) framework
2. What happens when counterfeiters forge RFID tags by copying the information from a valid tag or adding some well-formed format information to a new tag in the RFID system?
   - **A.** Middle Layers
   - **B.** DOS
   - **C.** Tracking
   - **D.** Sniffing
   - **E.** Counterfeiting
3. What tags are available for the cheapest price, compared with symmetric-key tags and public-key tags?
   - **A.** Symmetric-key tags
   - **B.** Public-key tags
   - **C.** Basic tags
   - **D.** Authenticated Routing tags
   - **E.** All of the Above
4. What uses a single key to perform both encryption and decryption?
   - **A.** False base cryptography.
   - **B.** Symmetric-key cryptography.
   - **C.** Eavesdropping cryptography
   - **D.** Man-in-the-Middle cryptography.
   - **E.** Passive cryptography.
5. What can provide security for RFID systems, but it is more suitable to be implemented in a closed environment?
   - **A.** HELLO Flood connectivity.
   - **B.** Denial-of-service attack connectivity.
   - **C.** Internet connectivity.
   - **D.** Symmetric-key cryptography.
   - **E.** All of the above.

Case Projects

Problem

Personnel and asset tracking in a health care environment, is a hypothetical case study to illustrate how RFID security might be implemented in practice. Although the case study is fictional, it is intended to resemble real-world activities, including how decision makers address common and expected RFID security problems and their solutions. The case study does not cover *all* of the aspects of RFID system engineering or operations that an organization may encounter in its RFID implementation, but rather a representative sample of salient issues. The case study follows.

The Fringe Science Research Center (FSRC) is a health care facility dedicated to the study of highly contagious diseases—those transmitted through casual human contact. The Center has 80 beds for patient care, a radiology unit with four rooms of sophisticated imaging equipment, and eight laboratories with various diagnostic and research capabilities. The Center confronts the same management issues as many hospitals, including locating portable diagnostic equipment when needed and accounting for missing assets. Another important concern is the ability to quickly locate patients and staff as they move about the facility. Poor asset management results in higher costs, reduced efficiency, and lower quality of care.

The mission of the FSRC also leads to specialized requirements. To prevent unnecessary outbreaks of disease and to understand how transmission occurs, FSRC needs to track the interactions among its staff, patients, and visitors. These tracked interactions provide useful information to researchers about who came into contact with whom and at what time. Additionally, the FSRC must alert caregivers of disease-specific protocols when they are in close proximity to particular patients, including prohibiting staff contact in some cases. It must track blood, urine, and stool samples from patient to laboratory. Finally, the FSRC would like to track the history of in-house diagnostic equipment and trace how the equipment is used to support patients throughout each day. Currently, paper processes are used to achieve these objectives, but they are very labor-intensive and error-prone, sometimes with fatal consequences.

FSRC executives tasked the FSRC's Chief Information Officer (CIO) to use RFID technology to improve the FSRC's traditional asset management function; as well as, meet its specialized requirements. Working with the FSRC executives, how did the CIO go about commissioning a project to reengineer FSRC business practices by using RFID technology as a primary tool to improve organizational performance?

Optional Team Case Project

Problem

Supply chain management of hazardous materials, is also a hypothetical case study to illustrate how RFID security might be implemented in practice. Although the case study is fictional, it is intended to resemble real-world activities, including how decision makers address common and expected RFID security problems and their solutions. The case study does not cover *all* of the aspects of RFID system engineering or operations that an organization may encounter in its RFID implementation, but rather a representative sample of salient issues. The case study follows.

The RAD corporation oversees the movement of radioactive research materials between production facilities, national laboratories, military installations, and other relevant locations. The RAD oversight of the supply chain for these materials involves many of the same issues as in most any other supply chain. RAD wants to know who is in possession of what quantity of materials at any given time. It also wants to locate materials at a site quickly, without having to search through numerous containers to find them. Bar code technology does not provide that capability.

Some of RAD's requirements are more unique. For instance, much of the transported radionuclide material must be closely monitored because extreme temperatures or excessive vibration can make it useless for its intended applications. Consequently, RAD wants temperature and vibration sensors to continuously measure environmental conditions and record readings on the tag. Additionally, the handling of RAD-regulated materials is a homeland and national security issue. If the materials were to fall into unauthorized hands, they could endanger the public welfare. So, with the preceding in mind, how would RAD's project team go about conducting a risk assessment?

Chapter 19

Optical Network Security

Lauren Collins
kCura Corporation

1. OPTICAL NETWORKS

The movement of data is not just about buying the best equipment out there. It is having the knowledge and logic to manipulate the hardware, create the configurations, shape the data, and possibly most important: secure that data. Having a vast amount of experience in getting data delivered quickly, a professional such as an architect for Electronic Trading embraces a strategy to capture the opportunities for the trader. This challenges the engineer to present opportunities for the trader, as well as to secure that formula to achieve long-standing success. However, when that data is compromised, a new obstacle presents itself. If everyone in the market has common knowledge on the trades and they have the fastest network, what sets them apart to capitalize on those markets?

Different types of businesses are confronted with different classes of security breaches. Cell phone providers may have an eavesdropping device attached to their network, which may leak news and confidential governmental matters if the proper tap is set. Mutual fund firms could have someone trying to access their quarterly statement prior to the release of information, which could be worth millions. Scanner taps may be present in International Interpol networks in order to gain knowledge of the location of government officials. Pharmaceutical players could also have a sniffer in their network to leak breaking news of a controversial drug recall.

Optical networks are potentially vulnerable to attacks based on the people who have access to the equipment and whether or not their curiosity to "tap" into the data supersedes their job function. Depending on the service provider architecture, equipment at each end may have multiple individuals representing several companies who access the equipment. This supplements the statement: "Assumptions should never be made that your data is safe." Both modern encryption methods and highly sophisticated methods to implement security procedures should be considered. This encryption protection derives from quantum mechanics, and military intelligence has monitored communications throughout the years, including tapping into undersea cabling. This chapter endeavors to familiarize readers with the various types of optical networks, how each type may be secured, how to identify vulnerabilities, and how to take corrective action.

Fiber

An optical fiber is a flexible, transparent fiber made of glass or plastic and is of comparable thickness to fishing wire. Engineers design networks utilizing optical fibers that permit transmissions over longer distances and at higher data rates than other forms of media communication. Fiber cabling is composed of two layers, the core and the cladding. Shown in Figure 19.1, the core is surrounded by the cladding layer, and the cladding layer has a higher index of refraction than the core.

Refraction of Light

As a light ray passes from one transparent medium to another, it changes direction; this phenomenon is called refraction of light. How much that light ray changes its direction depends on the refractive index of the mediums. In Figure 19.2, a ray's direction is altered when that ray enters the water.

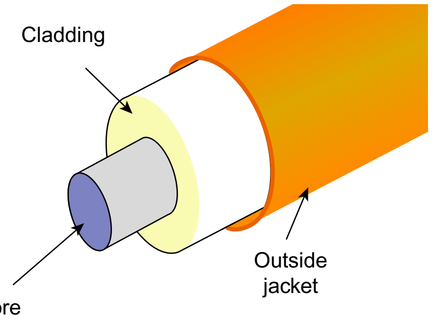

FIGURE 19.1 Fiber layers: cladding and core.

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00019-2

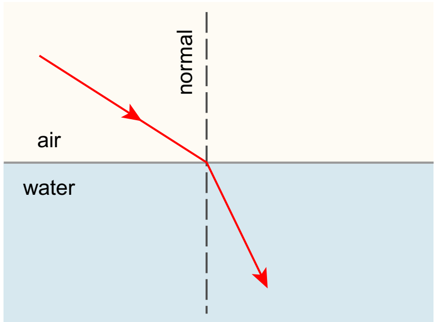

FIGURE 19.2 Refraction: Medium change from air to water alters the ray direction.

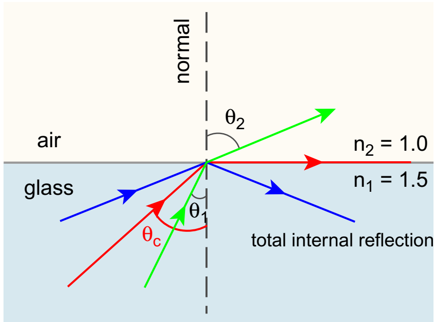

FIGURE 19.4 Total internal reflection: Angle of light affects transition to medium.

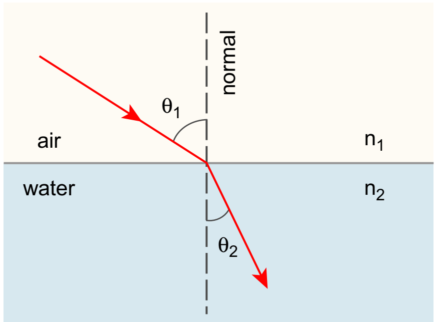

FIGURE 19.3 Snell's law portrays refractive indexes and angles.

Refractive Index

The refractive index is the speed of light in a vacuum (abbreviated $\boldsymbol{c}$, $\boldsymbol{c} = 299{,}792.458$ km/second) divided by the speed of light in a material (abbreviated $\boldsymbol{v}$). The refractive index measures how much a material refracts light. The refractive index of a material, abbreviated as $\boldsymbol{n}$, is defined as

$$\boldsymbol{n = c/v}$$

When light tries to pass from a lower to a higher index of refraction at the proper angle, the light will refract back instead. This series of refractions allows light to continuously travel through to the other end of the fiber. In 1621, the Dutch physicist Willebrord Snell derived the relationship between the different angles of light as it passes from one transparent medium to another. Figure 19.3 illustrates light passing from one transparent material to another; that light bends according to Snell's law, which is defined as [1]:

$$\boldsymbol{n}_1\ \mathbf{sin}(\theta_1) = \boldsymbol{n}_2\ \mathbf{sin}(\theta_2)$$

where:

$\boldsymbol{n_1}$ is the refractive index of the medium the light is leaving
$\boldsymbol{\theta_1}$ is the incident angle between the light beam and the normal (normal is 90° to the interface between two materials)
$\boldsymbol{n_2}$ is the refractive index of the material the light is entering
$\boldsymbol{\theta_2}$ is the refractive angle between the light ray and the normal

Note:
For the case of $\theta_1 = 0°$ (a ray perpendicular to the interface), the solution is $\theta_2 = 0°$ regardless of the values of n_1 and n_2. That means a ray entering a medium perpendicular to the surface is never bent.

The preceding is also valid for light going from a dense (higher n) to a less dense (lower n) material. The symmetry of Snell's law shows that the same ray paths are applicable in the opposite direction.

Total Internal Reflection

When a light ray crosses an interface into a medium with a higher refractive index, it bends toward the normal. Conversely, light traveling across an interface from a higher refractive index medium to a lower refractive index medium will bend away from the normal. This has an interesting implication: At some angle, known as the **critical angle** $\boldsymbol{\theta_c}$, light traveling from a higher refractive index medium to a lower refractive index medium will be refracted at 90°; in other words, it will be refracted along the interface.

If the light hits the interface at any angle larger than this critical angle, it will not pass through to the second medium at all. Instead, all of it will be reflected back into the first medium, a process known as total internal reflection, as shown in Figure 19.4.

The critical angle can be calculated from Snell's law, putting in an angle of 90° for the angle of the refracted ray $\boldsymbol{\theta_2}$. This gives $\boldsymbol{\theta_1}$:

$$\boldsymbol{\theta_1} = \mathbf{arcsin}[(\boldsymbol{n}_2/\boldsymbol{n}_1) * \mathbf{sin}(\theta_2)]$$

Since

$$\theta_2 = 90°$$

So

$$\sin(\theta_2) = 1$$

Then

$$\theta_c = \theta_1 = \arcsin(n_2/n_1)$$

For example, with light trying to emerge from glass with $n_1 = 1.5$ into air ($n_2 = 1$), the critical angle θ_c is arcsin(1/1.5), or 41.8. For any angle of incidence larger than the critical angle, Snell's law will not be able to be solved for the angle of refraction because it will show that the refracted angle has a sine larger than 1, which is not possible. In that case all the light is totally reflected off the interface, obeying the law of reflection.

Single Mode Versus Multimode

There are two types of fiber: single-mode fiber (SMF) and multimode fiber (MMF). Single-mode fiber has a narrow core, allowing only a single mode of light to propagate within the core. Inversely, multimode has a wide core and allows multiple modes of light to propagate. Both fibers are 125 microns in outside diameter. Single mode has a core size between 8 and 10 microns (μm). SMF will support distances up to several thousand kilometers, taking into consideration appropriate amplification, dispersion compensation, and tuning of the heat and light signal where the hardware and software are concerned. This mode requires more expensive, articulate light sources, typically operating at a wavelength of 1310 nanometers or 1550 nanometers (nm). Multimode has a core size between 62.5 μm OM1 and 50 μm OM2. The wider core allows for use of incoherent light sources utilizing many rays, or modes. MMF is conventionally more cost effective than SMF, and operates at a wavelength of 850 nm or 1310 nm. There is also an OM3 MMF with a core size of 50 μm. This cable is aqua in color, rather than the traditional orange, and is designed to achieve 10 Gbps at 300 m. Be advised that you cannot use single-mode fiber and connect to multimode hardware and vice versa. At a minimum, this could lead to a 20-dB loss, or 99 percent of the power and worst case could burn your equipment out and render it useless.

Layers Within Sites

When networking distant locations together, certain considerations need to be made so that data may flow and procedures can be put in place to ensure that access to equipment is done carefully. When considering that there are numerous physical locations in any organization, there are also multiple layers of communications that may take place at each of those locations. For example, Central Offices (COs) are organized into metropolitan areas and are usually interconnected by fiber. Equipment is placed in these buildings, and access may only derive from a customer accessing this or her first service CO, not diving further into the network layers or involving any access to other locations. Networks can further structure layers consisting of nodes, integrating switching components and/or the cross-connection of such equipment, linking those logical adjacencies to provide a streamlined solution.

The circuits that link layer 1 traffic may be presented as point-to-point (PTP), IP/Multiprotocol Label Switching (MPLS), or IP services (Internet). IP services are typically provided by MPLS, composed of routers. PTP services are provided through three different layers: (1) Wideband cross-connect (1.5 Mbps), (2) broadband cross-connect (45 Mbps−1 Gbps), composed of Optical Switching and SONET, and (3) Optical Multiplexing ROADM (2.5 Gbps and up). Figure 19.5 depicts a model in which two core services, IP and PTP, are introduced and the relationship among these services is delineated, as are their links and the circuits respective to associated layers.

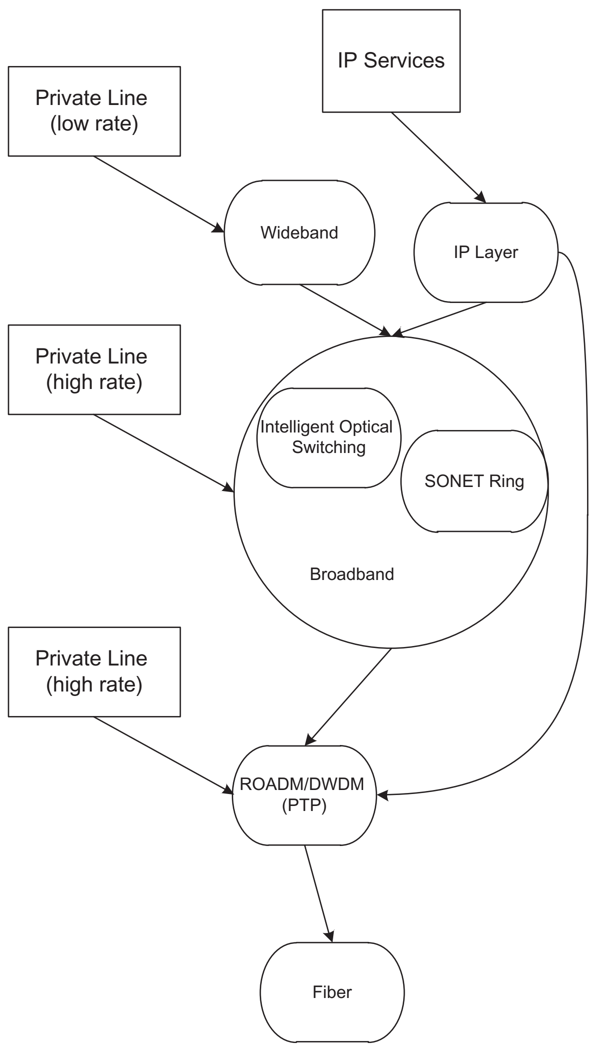

FIGURE 19.5 Geographical site: circuit layers.

2. SECURING OPTICAL NETWORKS

Information can be hidden in several dimensions of an optic: its phase, spatial frequency, wavelength, or the divergence of light. Since optical networks operate at such instantaneous transmission speeds, processing can offer advantages in matters of security.

Techniques

Tucking away an optically based message in one small section of a two-dimensional array, forces unauthorized users to find the messages' position before they can even start to decode it. Take this a bit further, and if you have an 8-bit optical system, one can decode as many as 256 gray shades, rather than dealing with those lovely one's and zero's that binary folks encode in hopes of securing information. Before that conspicuous user can begin the time-consuming, labor-intensive process to decode, he or she will need to gain access to the optic device in order to process the information. Altogether, these properties exponentially increase the mathematical possibilities for code-breakers to consider when they are confronted with optics and the techniques for encryption.

A typical optical system has components such as a light source, data, detectors, display devices, and sometimes, spatial light modulators. One can arrange these components in one of multiple configurations so that they can simulate the desired data.

Fourier Analysis

Jean Baptiste Joseph Fourier was a French mathematician and physicist known for introducing the Fourier series and corresponding applications to issues relevant to heat transfer and vibrations [2]. In 1822 Fourier presented his work on the flow of heat, which was based on two adjacent molecules proportional to one another, having a diminutive variance of their temperatures. This theory was amended several times by other contributors until 1888, when three works were published. One of the publications was purely mathematical, whereas the other two were, in essence, physics. Fourier had claimed that any function of a variable, whether continuous or discontinuous, could be expanded in a series of sines of multiples of the variable. Fourier's study, later found to be erroneous, showed that discontiguous functions are the sum of infinite series, such a breakthrough. This study of convergence was the fundamental one accepted for centuries, and the proposal of partial difference equation for conductive diffusion of heat is now taught to every student engaged in the study of mathematical physics.

Statement of the Equation

For functions $u(x,y,z,t)$ of three spatial variables (x,y,z) and the time variable t, the heat equation is:

$$\frac{\partial u}{\partial t} - \alpha\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right) = 0$$

In any coordinate system:

$$\frac{\partial u}{\partial t} - \alpha\nabla^2 u = 0$$

where α is a positive constant and Δ or ∇^2 denotes the Laplace operator. In the physical problem of temperature variation, $u(x,y,z,t)$ is the temperature and α is the thermal diffusivity. Per mathematical treatment, it is sufficient to consider the case $\alpha = 1$.

These equations are relative to this security discussion where such formulas are found to lead into the answer without even introducing decoding or breaking encryption. This equation, where the study of heat is concerned, finds a use in the Black-Scholes model. In financial mathematics, Black-Scholes is a mathematical model of a financial market that will contain assured derivative investment instruments. From this model, one can construe the formula that paved the way for derivatives to become commodities that could be traded in their own class. The economic housing explosion around 2006 encouraged options trading globally and ended in a subprime eruption, which cost banks hundreds of billions of dollars.

Conceptually, any system with a binary signal consists of bits that signify voltage or waves. This signal generally takes the form of a square wave that oscillates between two different states and those states representing two different voltage levels shown in Figure 19.6.

Square waves inherit their own set of difficulties when they are being sent at high frequencies, such as they would be when transmitted over fiber. Any waveform is comprised of an infinite integer of sine waves and/or cosine waves too, whether those waves are measured in the frequency of a square or harmonic wave. Consider 100 Mbit of a digital

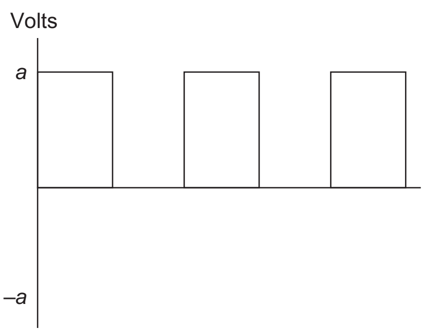

FIGURE 19.6 Square waves represent two states of voltage.

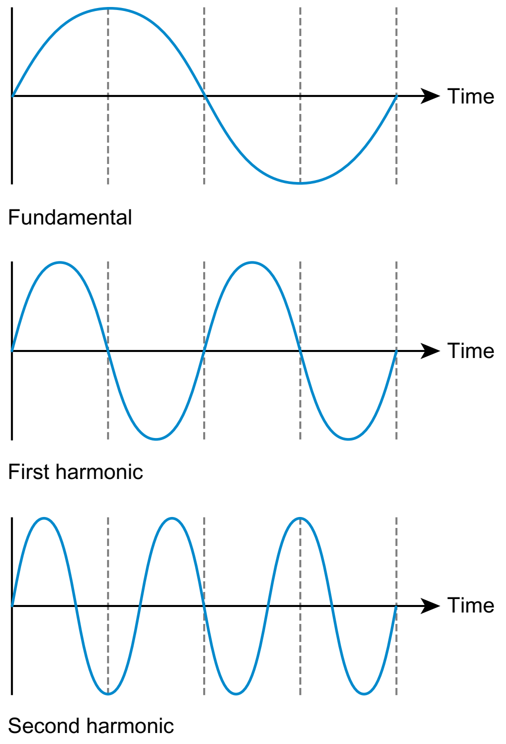

FIGURE 19.7 Frequency and waves cycle from positive to negative in both data and sound.

signal, which is similarly composed of a 100-MHz sine wave at 300 MHz, 500 MHz, 700 MHz, respectively, and so on. Relate this data whether you are streaming real-time stock quotes or recording music from an acoustic guitar, represented in Figure 19.7. The frequency is measured in cycles per second, or hertz (Hz). Frequencies unforeseeable to the human eye and inaudible to the human ear exist and can be portrayed dynamically and simultaneously through optics.

In order to analyze forms such as a digital square wave, mathematics conceptualizes in the process of Fourier analysis. We can use Fourier analysis in an equation that defines waves translated in time:

$$f(X) = a_0 + \sum_{n=1}^{\infty}\left[a_n \cos\left(\frac{n\pi X}{L}\right) + b_n \sin\left(\frac{n\pi X}{L}\right)\right]$$

$$a_0 = \frac{1}{2L}\int_{-L}^{L} f(X)\mathrm{dX}$$

$$a_n = \frac{1}{L}\int_{-L}^{L} f(X)\cos\left(\frac{n\pi X}{L}\right)\mathrm{dX}$$

$$b_n = \frac{1}{L}\int_{-L}^{L} f(X)\sin\left(\frac{n\pi X}{L}\right)\mathrm{dX}$$

where the values of a_n and b_n are effortlessly calculated. The summation sign Σ_n represents the sum over all the variables with an index n. For example, $\Sigma_n n^2 = 1^2 + 2^2 + 3^2 + \ldots$ The integral sign $\int^{L}{}_{-L}$ represents the sum over a continuous variable x from $x = -L$ to $x = +L$. A trivial example is $\int_{-L}^{L} \mathrm{dx} = 2\,\mathrm{L}$.

3. IDENTIFYING VULNERABILITIES

Optical fiber can be tapped more inexpensively and easily than ever, so a comprehensive, modular security strategy is necessary to ensure protection of a company's valuable information assets (see checklist: An Agenda for Action When Conducting an Optical Network Security Vulnerability Assessment). Some Wavelength Division Multiplexing (WDM) systems offer a cost-efficient capability to fully encrypt certain channels of traffic and monitor for intrusions at the physical layer. The result is a sophisticated security solution—without threatening degradation of the superior, low-latency performance for an organization's most demanding local and storage area network local area network (LAN) and storage area network (SAN) applications.

Signal Intelligence

Where data is ready and available, usually near where the cable terminates, it is easy to introduce a tap. Since taps are a cost-effective measure of hacking, and are not difficult to set up, this piece of hardware is more frequently used to access data. Based on knowledge, you can first gain access to the cabling and then extract light from the glass fibers. Most cabling is difficult to access since it may be underground, at the ocean floor, covered in concrete, or running through a conduit in elevator shafts. However, an adequate amount of cabling is accessible for those willing to look. Many companies boast about their fiber networks and list their fiber paths online, making them easy for hackers to locate. Hone in on the location of the cable, gain access to it, and pull data from the cable. The hack is now a success.

Bending is a process through which you insert a clip-on coupler. There is no interruption to the light signal, and only a small amount of light is leaked through the polymer cabling. Once the light has been retrieved, data can be captured by a photo detector. The next piece of equipment needed sniffs data off of the glass fibers. This device facilitates the connection to a network interface card (NIC), which will capture packets and filter data for information corresponding to IP, MAC addresses, DNS information, and any keywords in the data passed without encryption. This method would cost less than $2000 for the equipment to be acquired and positioned. Any firm that does not rely on data down to the nanosecond would

An Agenda for Action when Conducting an Optical Network Security Vulnerability Assessment

A security vulnerability assessment evaluates an optical network system's security performance; measures security trends and exceptions related to security policy, procedures, and user access; performs an audit of intrusion-detection data; and provides recommendations for improvement by conducting the following activities (check all tasks completed):

_____**1.** Conduct a planning meeting to set expectations and milestones and to define deliverables.

_____**2.** Define criteria for network security optimization, including utilization, fault conditions, error thresholds, and throughput.

_____**3.** Collect and analyze data for trends and exceptions that may impact network security.

_____**4.** Monitor and inspect security logs to trend usage of systems and suspicious activity.

_____**5.** Review network security component placement and configuration for optimal load distribution and traffic management.

_____**6.** Assess security performance against established criteria.

_____**7.** Provide impact analysis of new software versions, features, and configurations.

_____**8.** Provide hardware and software recommendations to optimize system and network performance.

_____**9.** Provide recommendations for network and security component tuning,,including system optimization, filtering, route redistribution, trunk and port configuration, and protocol, policy, and feature configuration.

_____**10.** Identify and measure the optical network security system for trends and exceptions related to security policy, procedures, and user access.

_____**11.** Assess the (advanced technology) security system performance against the established baseline and analyze for areas of improvement.

_____**12.** Analyze access-control policies and make recommendations for improvement.

_____**13.** Develop a Security Assessment Report highlighting recommendations for improving security.

_____**14.** Present and review the Security Assessment Report.

not notice any change in accessing their data when this procedure of tapping data has taken place.

Splicing is another method that is not as functional and, though seldom used, can result in detection due to the transient interruption of the light. Consider a cable that is capable of transporting 100 million concurrent connections; those connections require instantaneous signal rerouting to maintain network integrity. Splicing would interrupt that fiber integrity, even for a millisecond, and the connection would noticeably drop and potentially converge depending on the network routing.

Access to Equipment

Many firms collocate their infrastructure at a secured data center. These facilities utilize access lists to allow individuals access to the site and additionally into secured areas. Some of these areas are located in shared space, where a firm may have *n* number of cabinets in a large area among other firms. The cabinets may have locks on them to secure the equipment from others in that shared space, or an escort may be mandated for particular areas.

Regarding Metro facilities that are only open to Telecom companies, there are certainly areas of access that may be open to others. Technicians may be on-site to repair or to maintain equipment. While many organizations are putting protocols in place to secure equipment and data, these facilities are open for both ease of access and for cross-functional work to be completed. One method to troubleshoot line latency or recurring line outages may be to tap that circuit, granting permission for the placement of the equipment that could cross the line, obscuring justice.

4. CORRECTIVE ACTIONS

All fiber runs should be enclosed and protected from anyone who might try to gain access to the cabling. The room where the cable terminates, known as the demarcation point, is a point where some may find data readily accessible.

Securing Equipment

Chapter 60 delves much deeper into the concept of securing the infrastructure. Wiring closets, public areas, and junction boxes should be secured and monitored.

Encryption

Sensitive data should always be encrypted to protect that data in the event an attacker gains access to the data. There are particular vendors who develop instruments to protect optical networks; such instruments offer protection at the physical layer as well as intrusion

detection. These vendors identify possible threats and alert administrators of possible events, including excessive packet-receiving overloads, signal loss, transitory loss of power, and malicious infringement. One solution offered, though cost sensitive, is a real-time protocol agnostic monitoring system for optical networks. When an intrusion is detected, the path is shut down and traffic is rerouted to an alternate path. These independent solutions offer protection against corporate eavesdropping, government and financial espionage, network disturbances, and terrorism.

At this point, detection solutions notwithstanding, encryption of transmitted data is the only measure to prevent information from being pilfered from optical networks. The trend is leaning toward encryption at the data layer, which reduces latency and overhead associated with transporting large amounts of data at high speeds. Some make the mistake of encrypting data at the data layer and also at the physical layer, in the transmission of the data. While both may seem to cover all bases, only encryption is needed since the hindrance put forth will deter eavesdroppers. This will also save money where one will not have to add to latency and the overhead to support and manage additional equipment.

5. SUMMARY

An optical signal undergoes many transmission impairments throughout its entire path in an optical network. The peculiar behavior of the transmission medium and active/passive elements in the network makes an optical network vulnerable to unscrupulous attacks, thereby jeopardizing the security of information. In optical networks, data travel optically from source to destination without any optical-electrical conversions, thereby making the networks transparent to modulation format, bitrate, and protocol. This transparency poses many survivability vulnerabilities to attacks. This chapter discussed in detail the possible attack scenarios at the physical layer and also presented a conceptual modeling of attack problems and possible protection schemes in optical networks. However, attacks exploiting device characteristics necessitate comparatively more involved diagnostic expertise, complex remedial measures, and even more systematic detection schemes and control protocols. Future research will deal with the issue of practically feasible attack detection and restoration approaches.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Optical networks are not vulnerable to attacks based on the people who have access to the equipment and whether their curiosity to "tap" into the data supersedes their job function.
2. True or False? An optical fiber is a flexible, transparent fiber made of glass or plastic and is of comparable thickness to fishing wire.
3. True or False? As a light ray passes from one transparent medium to another, it does not change direction; this phenomenon is called refraction of dark.
4. True or False? The refractive index is less than the speed of light in a vacuum (abbreviated $\boldsymbol{c}$, $\boldsymbol{c} = 299{,}792.458$ km/second) divided by the speed of light in a material (abbreviated $\boldsymbol{v}$).
5. True or False? There are two types of fiber: single-mode fiber (SMF) and multimode fiber (MMF).

Multiple Choice

1. The circuits that link layer 1 traffic may be presented as:
   A. spoofing.
   B. point-to-point (PTP).
   C. application programming interfaces.
   D. network areas.
   E. Extensible Authentication Protocol (EAP) framework.
2. What type of waves inherit their own set of difficulties when being sent at high frequencies (such as they would be when transmitted over fiber)?
   A. Square
   B. Rectangle
   C. Triangle
   D. Octagon
   E. Trapizoid
3. In order to analyze forms such as a digital square wave, mathematics conceptualizes in the process of:
   A. Security Vulnerability Analysis.
   B. Wavelength Division Multiplexing.
   C. Signal Intelligence.
   D. Fourier analysis.
   E. All of the above.
4. What is the process of inserting a clip-on coupler?
   A. Splicing
   B. Accessing
   C. Bending
   D. Correcting
   E. Cabling
5. Sensitive data should always be ________ to protect that data in the event an attacker gains access to the data.
   A. encrypted
   B. protected

C. corrected
D. monitored
E. all of the above

EXERCISE

Problem

Is it possible to secure the files stored on a network attached storage (NAS) optical storage server?

Hands-On Projects

Project

How does optical network security work across the multiple protocols?

Case Projects

Problem

Can optical network security be controlled down to the directory level?

Optional Team Case Project

Problem

Can optical network security be set on a virtual volume?

1. OPTICAL WIRELESS SYSTEMS OVERVIEW

In this section, we examine the origins of using light as a means of communication, and we discuss how, over time, it developed into free space optic (FSO) technology. This section will also cover the use of the technology.

History

The use of light and optics is long standing. The ancient Greeks used their polished shields to send reflected light signals while in battle. In 1880, Alexander Graham Bell and his assistant, Charles Sumner Tainger, jointly created a device they called a photophone, or radiophone. Using it, they could transmit sound on a beam of light. The device was based on the photovoltaic properties of crystalline selenium and worked very similarly to the telephone. Bell did not, however, predict the laser or fiber optics, which needed to predicate any potential success of such a device. World War II saw the use of the invention for secure communication. Early on, its users recognized that clear, targeted, line-of-sight communication, invisible to everyone else, allowed for a high degree of security. FSO technology is inherently secure primarily because of this. It wouldn't be until the 1960s and the invention of lasers that this form of communication would mature into Bell's 1880s vision.

Today

FSO uses optical pulse-modulated signals—light—to transmit data from point to point. The technology is similar to fiber optics, with the exception that instead of being contained in glass fiber, the signal is transmitted through varying degrees of atmospheric conditions. Each FSO unit consists of an optical transmitter and receiver with full duplex capability. This means it is bidirectional.

Typically, these devices are mounted on buildings. Part of the security of these devices is, of course, ensuring that no harm or damage can come to the device, due to its perceived attractiveness by natural aviary populations (make sure you can keep pigeons off of it). The devices contain an array of optics that is used to signal between the device pair at distances of up to several kilometers.

Because these systems are mounted on buildings and because (conceivably) something could happen that could cause a unit to point or be directed into human (or even pigeon) eyes, there are some safety considerations. FSO systems operate in the infrared range. When discussing these devices, and the range in which they operate, the term *wavelength* is used.

Theory of Operation

It is common knowledge that radio frequency (rf) transmissions are easily intercepted and that the technology of securing the transmissions can, if it is secured at all, usually be circumvented, given enough time and effort. It takes little effort to simply drive around and find an "open" wireless connection, even though Light is both a wave and a particle, but most often is discussed in terms of wavelength. Generally, FSO uses infrared (IR), optical light-emitting diode (LED) laser technology at between 780 and 1550 nm. The higher ranges are thought to be less damaging to the cornea as the beam is absorbed by the cornea and never strikes the retina.

The greatest challenge that faces widespread acceptance of FSO is atmospheric conditions. Factors such as fog, smog, heavy rain, or even clouds of dust raised by construction or in areas near desert locales are detrimental to the optical signal. The greater the distance that the beam attempts to traverse, the greater the likelihood that it will fail. Additionally, scintillation—viewed by human eyes as "heat mirages"—is a perturbation in the homogeneous atmospheric density that can significantly distort the photonic transmission. Units with adaptive power will reduce the power to the laser in clear weather and increase it in inclement conditions. Adaptive power features will also increase the life span of the units. Many units are built with features that will increase the physical security. Features such as the following all contribute to

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00020-9

increase the security by significantly reducing overshoot signals:

- Adaptive power—prevents overpowering during clear weather
- High frequency—prevents the use of commercially available optics to detect the signal
- Narrow beamwidth—reduces overshoot footprint
- Higher quality optics—prevents a narrower overshoot footprint

Placement on buildings can determine the amount of security as well as signal degradation due to atmospheric conditions. Higher elevations on buildings may increase the amount of disruption to fog; lower elevations may increase the amount of disruption to construction activities like severe dust. Placement should also ensure that the unit has some sort of backstop that can prevent overshoot footprint.

Finally, as it relates to physical security, the diffraction grating effect of shining a light through a small hole must be considered. As any sophomore physics student knows, the equation of light diffraction through an aperture is:

$$I = I_0\left(\frac{\sin\beta}{\beta}\right)^2$$

where

$$\beta = \frac{\pi W \sin\theta}{\lambda}$$

W = the size of the aperture.

As can be seen, as the aperture gets larger and the wavelength gets smaller, the central disk of illumination varies inversely with the size of the aperture. An FSO manufacturer that simply assembles parts from various manufacturers without consideration of diffraction grating will be more vulnerable to overspread than a conscientious manufacture that has thoroughly engineered its product.

2. DEPLOYMENT ARCHITECTURES

Deployment of the technology varies. The commonly used variations are mesh, ring, point to multipoint (PMP), and point to point (P2P). Some concern over building movement may be appropriate—there are devices capable of autocorrecting up to a few degrees of range. Most devices are designed with movement-handling capabilities. Building architects may have more information; it would be very disappointing to install a system in July, only to find out, nearly nine months later, that March through May winds cause unacceptable disruptions in service, caused by building sway.

Mesh

In a mesh architecture, every node is connected to every other node in a mesh-like lattice work of connections (see Figure 20.1). An increase in the number of nodes increases the quality of the mesh. Mesh networks offer a high degree of reliability. Mesh and ring architectures are larger scale, metropolitan-style deployments that may be used by large carriers and service providers.

Ring

Large cities, such as Hong Kong, may use ring architecture to deliver quality, high-bandwidth Internet services to the entire city. Ring architecture is a blend of mesh and Point to Point/point-to-point (PTP) (see Figure 20.2). With a broad geographical deployment, the ring itself resides at the center, near or at a large communications trunk, or several. It may or may not link multiple trunk sites for redundancy, which also increases the diameter of the ring to extend the range over the area. Communication points are then established as links that radiate outward from the ring, like the spokes of a wheel.

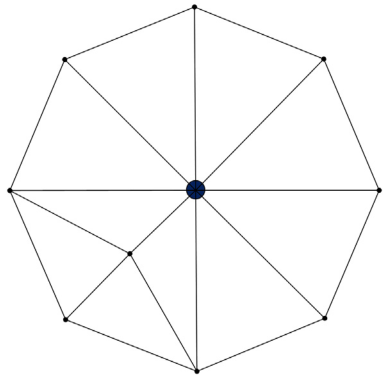

FIGURE 20.1 In a mesh schema, all points are interconnected. This provides a high degree of redundancy.

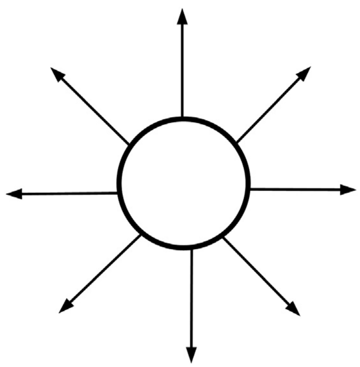

FIGURE 20.2 In a ring schema, a heavy-duty, high-bandwidth ring exists at the center. This provides a high degree of redundancy, as well as pushing the threshold for distance and strength of signal.

Point to Point

Point-to-point architecture comes in two flavors: PTP and PMP. As the names imply, the only difference lay in the one-to-one relationship versus a one-to-many relationship. This architecture primarily suits smaller deployments, such as an organization that may have multiple office locations or an office that has set up space across the street.

In a PTP network, multiple single connections are chained together, linearly, to increase the range of the network. Perhaps the only connection to be made is across town, or perhaps multiple locations are served along the way. It effectively increases the range of the product or defeats the shortened range that may occur during inclement conditions.

In a PMP schema, all connections to various locations radiate outward from a central location. A single node acts as the source, with a central communications closet in the building serving to link the devices at the central location. For example, by placing the optical wireless devices at all four sides of a single, hub building, you can extend the network to surrounding buildings. Such a deployment would be most suitable for organizations with campus-styled building layouts. Figure 20.3 illustrates the connection points of such an arrangement.

3. HIGH BANDWIDTH

FSO devices boast speeds of up to 10 Gbps in an unhindered atmosphere. Bandwidth decreases in the presence of smog and fog down to complete loss of signal. For this reason, when selecting FSO, it is important to consider the local weather and the distances involved.

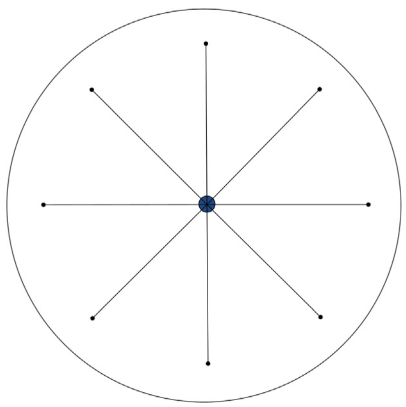

FIGURE 20.3 In a PMP schema, a single, central trunk provides high-bandwidth service to multiple, closely linked optical wireless transmitters. This provides a low-cost solution to providing high-bandwidth network services in a small geographical area, where cost savings is more important than redundancy or high availability.

4. LOW COST

Security is expensive. The larger the physicality of the surface area, the greater is the area that needs protection from attack. Assuming that line of sight and lease rights are forthcoming and easily procured, setting up a land-based metropolitan network in a city such as Chicago could be very expensive. The price difference of using fiber versus FSO in an installation to connect two offices that are 400 m apart is not just a small percentage. It is several orders of magnitude more expensive to install fiber.

5. IMPLEMENTATION

In theory, FSO has great potential to become far more commonplace and enjoy much greater acceptance in the information technology community than it currently enjoys. At the time of this writing, FSO installations can be found in places such as corporate and educational campuses.

Future use could see the removal of wired communications across long distances in open country, with tall poles housing FSO equipment. It is common knowledge that the technology has already been successfully used in space communications and that Artemis, the European Space Agency Advanced Relay and Technology Mission Satellite, successfully linked with an aircraft at a distance of over 40,000 km. The use of optical boosting equipment could introduce even greater adoption in long-distance (many millions of miles) communications with deep space missions.

High data rates, lightweight equipment, low-energy requirements, little interference, and nearly guaranteed clear and unobstructed paths between space platforms makes space the ideal environment for FSO networks. They would also be somewhat tap proof, though it is conceivable that an enemy satellite could interpose and successfully relay the signal, undetected, the whole while recording and transmitting it back to Wreaking Havoc headquarters (HQ).

6. SURFACE AREA

Microwave and radio frequency (RF) antennas that are typically used to interconnect remote stations have a radial dispersion of 5 to 25 degrees. The actual wavelength of light for optical wireless is in the near-infrared range of 800−1500 nm.

Narrow beams are usually less than 0.5 degrees. By using the diagram and formula given in Figure 20.4, the approximate spread of the beam can be calculated providing the distance is known.

Generally speaking, optical wireless devices operate at the same wavelength as fiber-optic networks. Thus, a

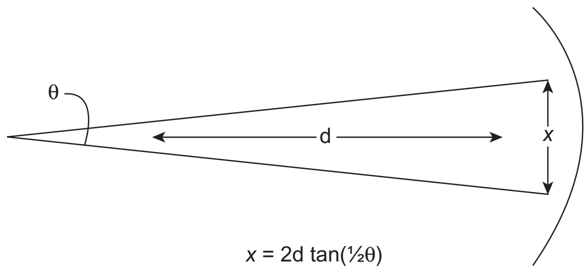

FIGURE 20.4 The width of the broadcast at x distance can be calculated using simple trigonometry. Different manufacturers boast different theta and use this formula to calculate the spread based on equipment specifications.

small wavelength creates frequencies in the several hundred terahertz (THz) range. This is much higher than commercial microwave communications. The lower power and tighter beam of the wireless optics prevent wide angles of reflection, which can be intercepted in an attack (see checklist: An Agenda for Action When Implementing the Security of FSO). Government organizations were among the first to recognize that the greater ability to control the wireless beam inherently meant a higher degree of freedom. The 128 and 256 advanced encryption standard is frequently used in microwave transmissions; while this is all well and good, many are concerned that it can be broken.

To intercept an optical wireless system, the hacker must know the location of either the origin or the target. The intruder must also have unhindered access to a location where he can set up his electronic equipment without being caught or disturbed. Since this location is usually a commercial location, at an elevation well above ground, the ability to insert becomes tremendously more challenging. FSO devices also employ multiplex, bidirectional signals. If the insertion is occlusive, then the units *know* when the signal has been disrupted. They will not continue to broadcast without the reverse bias feedback that indicates a successful connection. The interloper will only intercept connections establishing signals.

Additionally, the very high installations that are typical of optical wireless present additional challenges. But what about light scattered from rain, fog, dust, aerosol, or the like? Optical wireless transmissions use extremely low power levels, but the main reason for discounting this possible attack is the scattering of light in many different directions from the transmitted path.

The amount of radiation that can be collected with a detector capable of processing the signal is well beneath the range of what most detectors would consider noise. Because the beam is a laser, once the beam is scattered, the scattered photons still maintain their cohesion. However, being lasers, they tend to move in a very straight line with little incoherence. Capturing enough of the scattered light would require a collector that encapsulates the entire beam, and even then, it may not be enough. Ultimately, though, if the fog is such that one can see the actual beam (imagine a laser pen shining through fog), then it is conceivable that a collector could be designed that would be able to read the signal and translate its longitudinal section. The most likely scenario is that such an intercept device would only capture useless noise and would be so large as to make it extremely noticeable and unwieldy.

Lastly, a hacker could conceivably parachute onto the roof of a building and set his or her intercept device down on top of or next to the network FSO he or she wished to crack. For this reason, take the following precautions:

- FSOs should have backstops to prevent overshoot to neighboring office windows or rooftops.
- They should be mounted in difficult to reach places.
- They should have physical security such as keycard and/or biometric access.
- They should be protected by motion detection systems and motion-activated video surveillance.

An Agenda for Action when Implementing the Security of FSO

The five items in this checklist are, in the author's experience; the most important and critical things to address (and they are listed in order of priority) in any project that aspires to achieve true security of the physical infrastructure. The easiest way to gain access to classified access is always the first way that will be attempted by those who wish to gain unauthorized access. So, assuming that data access prevention through traditional hacking attacks is in place, the key to security of FSO lies in the following (check all tasks completed):

_____**1.** *Intrusion alerts*: When a signal is lost or disrupted, make sure your management software is capable of pinpointing when and where the interruption occurred.

_____**2.** *Entrusted access:* Make sure that, either real or verified, the people working with the data are not selling it out the back door—that they are incorruptible.

_____**3.** *Physical security of hardware:* Prevent actual physical access by unauthorized personnel.

_____**4.** *Eavesdropping on transmissions*: Make sure that any mechanism that collects the data in transit is thwarted.

_____**5.** *Data security*: Make sure that the data is encrypted, so that should it be intercepted it cannot be understood.

7. SUMMARY

The advantages of FSO technology are easily summarized. Its security is achieved primarily through the difficulty in interception of the signal. Additional security can easily be introduced in the form of traffic encryption, though this will subtract from the overall, available bandwidth. Deployment of the technology is easy because large areas can be quickly spanned with the installation of just two devices. Additionally, the technology is unaffected by electromagnetic interference, and it has low rates of error in the transmission, which means higher overall bandwidth. It also has no licensing fees, unlike microwave transmissions, and with a range of 2 KM, this is a very attractive feature.

While it does face its challenges, such as fog and very dense weather, in such areas where this is common, it could serve to offer a layer of Disaster Recovery (DR) protection. If land links are compromised due to earthquake, flood, or hurricane, FSO can offer a way of bringing signal in to an area quickly from an unaffected area.

Regardless of the configuration used, and its strengths and weaknesses, FSO is a technology that should be examined and considered as a potentially essential element in any large-area communications architecture. In the end, it is important to realize that security is never a *one-step* task. It has multiple dimensions, and every product has its security weaknesses and strengths. The most important aspect is to choose a technology that, in the existing enterprise, meshes well with existing security features, or is capable of being adapted easily and quickly to them.

The most attractive feature of FSO systems is the tremendous transmission security provided by the very narrow width of the beam used. Lasers can be aimed with a great deal of precision, and considering that the aperture of a laser beam that is very much larger than the actual wavelength of the laser, diffraction interference is minimal. This prevents even further scattering that could potentially be used to even detect that laser transmissions are occurring. The combination of keeping the location of the transceivers secret, the lack of distortion scattering, and the narrow beamwidth offers a high level of security in that the beam is virtually undetectable.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solution Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? FSO uses optical pulse-modulated signals—light—to transmit data from point to point.
2. True or False? It is not common knowledge that radio frequency transmissions are easily intercepted and that the technology of securing the transmissions can, if it is secured at all, usually be circumvented, given enough time and effort.
3. True or False? Most devices are not designed with movement-handling capabilities.
4. True or False? In a mesh architecture, every other node is connected to every other node in a mesh-like lattice work of connections.
5. True or False? Ring architecture is a blend of mesh and PTP.

Multiple Choice

1. What architecture comes in two flavors: PTP and PMP?
   A. Spoofing
   B. Point-to-point
   C. Application programming interfaces
   D. Network areas
   E. Extensible Authentication Protocol (EAP) framework
2. What devices boast speeds of up to 10 Gbps in an unhindered atmosphere?
   A. SSO
   B. RSO
   C. FSO
   D. OSO
   E. TSO
3. The larger the physicality of the surface area, the greater is the area that needs protection from:
   A. attack.
   B. high expenses.
   C. price differences.
   D. lease rights.
   E. All of the above.
4. In theory, what has great potential to become far more commonplace and enjoy much greater acceptance in the information technology community than is currently the case?
   A. Splicing
   B. Accessing
   C. Bending
   D. FSO
   E. Cabling
5. Microwave and RF antennas that are typically used to interconnect remote stations have a radial dispersion of:
   A. 5−20 degrees.
   B. 5−30 degrees.
   C. 5−35 degrees.
   D. 5−40 degrees.
   E. 5−25 degrees.

Chapter 21

Information Security Essentials for IT Managers: Protecting Mission-Critical Systems

Albert Caballero
Terremark Worldwide, Inc.

1. INFORMATION SECURITY ESSENTIALS FOR IT MANAGERS, OVERVIEW

Information security management as a field is ever increasing in demand and responsibility because most organizations spend increasingly larger percentages of their IT budgets in attempting to manage risk and mitigate intrusions, not to mention the trend in many enterprises of moving all IT operations to an Internet-connected infrastructure, known as enterprise cloud computing.[1] For information security managers, it is crucial to maintain a clear perspective of all the areas of business that require protection. Through collaboration with all business units, security managers must work security into the processes of all aspects of the organization, from employee training to research and development. Security is not an IT problem, it is a business problem.

Information security means protecting information and information systems from unauthorized access, use, disclosure, disruption, modification, or destruction[2]

Scope of Information Security Management

Information security is a business problem in the sense that the entire organization must frame and solve security problems based on its own strategic drivers, not solely on technical controls aimed to mitigate one type of attack. The evolution of a risk-based paradigm, as opposed to a technical solution paradigm for security, has made it clear that a secure organization does not result from securing technical infrastructure alone. Furthermore, securing the organization's technical infrastructure cannot provide the appropriate protection for these assets, nor will it protect many other information assets that are in no way dependent on technology for their existence or protection. Thus, the organization would be lulled into a false sense of security if it relied on protecting its technical infrastructure alone.[3]

CISSP Ten Domains of Information Security

In the information security industry there have been several initiatives to attempt to define security management and how and when to apply it. The leader in certifying information security professionals is the Internet Security Consortium, with its CISSP (see sidebar, "CISSP Ten Domains: Common Body of Knowledge") certification.[4]

In defining required skills for information security managers, the ISC has arrived at an agreement on ten domains of information security that is known as the *Common Body of Knowledge* (CBK). Every security manager must understand and be well versed in all areas of the CBK.[5]

In addition to individual certification there must be guidelines to turn these skills into actionable items that can be measured and verified according to some international standard or framework. The most widely used standard for maintaining and improving information security

CISSP Ten Domains: Common Body of Knowledge

- *Access control.* Methods used to enable administrators and managers to define what objects a subject can access through authentication and authorization, providing each subject a list of capabilities it can perform on each object. Important areas include access control security models, identification and authentication technologies, access control administration, and single sign-on technologies.
- *Telecommunications and network security.* Examination of internal, external, public, and private network communication systems, including devices, protocols, and remote access.
- *Information security and risk management.* Including physical, technical, and administrative controls surrounding organizational assets to determine the level of protection and budget warranted by highest to lowest risk. The goal is to reduce potential threats and money loss.
- *Application security.* Application security involves the controls placed within the application programs and operating systems to support the security policy of the organization and measure its effectiveness. Topics include threats, applications development, availability issues, security design and vulnerabilities, and application/data access control.
- *Cryptography.* The use of various methods and techniques such as symmetric and asymmetric encryption to achieve desired levels of confidentiality and integrity. Important areas include encryption protocols and applications and Public Key Infrastructures.
- *Security architecture and design.* This area covers the concepts, principles, and standards used to design and implement secure applications, operating systems, and all platforms based on international evaluation criteria such as Trusted Computer Security Evaluation Criteria (TCSEC) and Common Criteria.
- *Operations security.* Controls over personnel, hardware systems, and auditing and monitoring techniques such as maintenance of AV, training, auditing, and resource protection; preventive, detective, corrective, and recovery controls; and security and fault-tolerance technologies.
- *Business continuity and disaster recovery planning.* The main purpose of this area is to preserve business operations when faced with disruptions or disasters. Important aspects are to identify resource values, perform a business impact analysis, and produce business unit priorities, contingency plans, and crisis management.
- *Legal, regulatory, compliance, and investigations.* Computer crime, government laws and regulations, and geographic locations will determine the types of actions that constitute wrongdoing, what is suitable evidence, and what type of licensing and privacy laws your organization must abide by.
- *Physical (environmental) security.* Concerns itself with threats, risks, and countermeasures to protect facilities, hardware, data, media, and personnel. Main topics include restricted areas, authorization models, intrusion detection, fire detection, and security guards.

is ISO/IEC 17799:2005. ISO 17799 (see Figure 21.1) establishes guidelines and principles for initiating, implementing, maintaining, and improving information security management in an organization.[6]

A new and popular framework to use in conjunction with the CISSP CBK and the ISO 17799 guidelines is ISMM. ISMM is a framework (see Figure 21.2) that describes a five-level evolutionary path of increasingly organized and systematically more mature security layers. It is proposed for the maturity assessment of information security management and the evaluation of the level of security awareness and practice at any organization, whether public or private. Furthermore, it helps us better understand where, and to what extent, the three main processes of security (prevention, detection, and recovery) are implemented and integrated.

ISMM helps us better understand the application of information security controls outlined in ISO 17799. Figure 21.3 shows a content matrix that defines the scope of applicability between various security controls mentioned in ISO 17799's ten domains and the corresponding scope of applicability on the ISMM Framework.[7]

What is a Threat?

Threats to information systems come in many flavors, some with malicious intent, others with supernatural powers or unexpected surprises. Threats can be deliberate acts of espionage, information extortion, or sabotage, as in many targeted attacks between foreign nations; however, more often than not it happens that the biggest threats can be forces of nature (hurricane, flood) or acts of human error or failure. It is easy to become consumed in attempting to anticipate and mitigate every threat, but this is simply not possible. Threat agents are threats only when they are provided the opportunity to take advantage of a vulnerability, and ultimately there is no guarantee

that the vulnerability will be exploited. Therefore, determining which threats are important can only be done in the context of your organization. The process by which a threat can actually cause damage to your information assets is as follows: A threat agent *gives rise to* a threat that *exploits* a vulnerability and can *lead to* a security risk that *can damage* your assets and *cause* an exposure. This can be *counter-measured by* a safeguard that *directly affects* the threat agent. Figure 21.4 shows the building blocks of the threat process.

Common Attacks

Threats are exploited with a variety of attacks, some technical, others not so much. Organizations that focus on the technical attacks and neglect items such as policies and procedures or employee training and awareness are setting up information security for failure. The mantra that the IT department or even the security department, by themselves, can secure an organization is as antiquated as black-and-white television. Most threats today are a mixed blend of automated information gathering, social engineering, and combined exploits, giving the perpetrator endless vectors through which to gain access. Examples of attacks vary from a highly technical remote exploit over the Internet, social-engineering an administrative assistant to reset his password, or simply walking right through an unprotected door in the back of your building. All scenarios have the potential to be equally devastating to the integrity of the organization. Some of the most common attacks are briefly described in the sidebar, "Common Attacks."[10]

Impact of Security Breaches

The impact of security breaches on most organizations can be devastating; however, it's not just dollars and cents that are at stake. Aside from the financial burden of

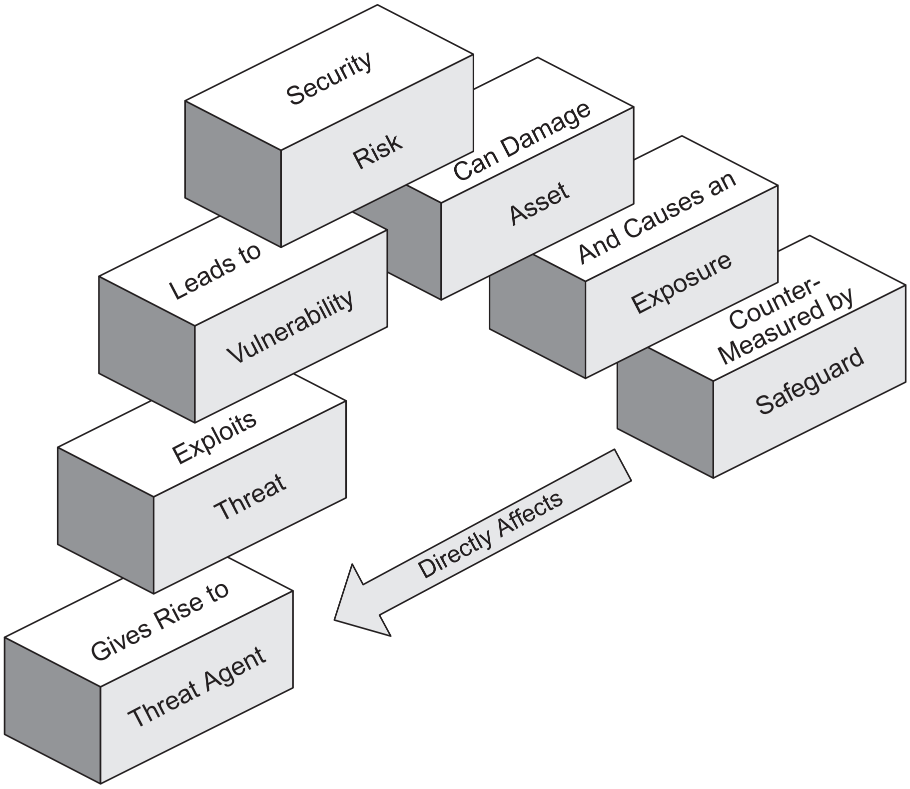

FIGURE 21.4 The threat process.

Common Attacks

- *Malicious code (malware).* Malware is a broad category; however, it is typically software designed to infiltrate or damage a computer system without the owner's informed consent. As shown in Figure 21.5, the most commonly identifiable types of malware are viruses, worms, backdoors, and Trojans. Particularly difficult to identify are root kits, which alter the kernel of the operating system.
- *Social engineering.* The art of manipulating people into performing actions or divulging confidential information. Similar to a confidence trick or simple fraud, the term typically applies to trickery to gain information or computer system access; in most cases, the attacker never comes face to face with the victim.
- *Industrial espionage.* Industrial espionage describes activities such as theft of trade secrets, bribery, blackmail, and technological surveillance as well as spying on commercial organizations and sometimes governments.
- *Spam, phishing, and hoaxes.* Spamming and phishing (see Figure 21.6), although different, often go hand in hand. Spamming is the abuse of electronic messaging systems to indiscriminately send unsolicited bulk messages, many of which contain hoaxes or other undesirable contents such as links to phishing sites. Phishing is the criminally fraudulent process of attempting to acquire sensitive information such as usernames, passwords, and credit card details by masquerading as a trustworthy entity in an electronic communication.
- *Denial-of-service (DoS) and distributed denial-of-service (DDoS).* These are attempts to make a computer resource unavailable to its intended users. Although the means to carry out, motives for, and targets of a DoS attack may vary, it generally consists of the concerted, malevolent efforts of a person or persons to prevent an Internet site or service from functioning efficiently or at all, temporarily or indefinitely.
- *Botnets.* The term *botnet* (see Figure 21.7) can be used to refer to any group of bots, or software robots, such as IRC bots, but this word is generally used to refer to a collection of compromised computers (called zombies) running software, usually installed via worms, Trojan horses, or backdoors, under a common command-and-control infrastructure. The majority of these computers are running Microsoft Windows operating systems, but other operating systems can be affected.

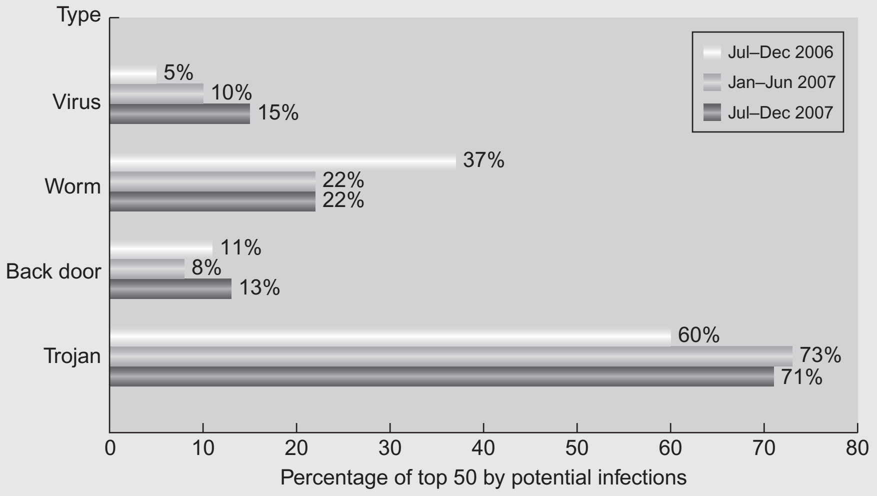

FIGURE 21.5 Infections by malicious code type, CSI/FBI report, 2008[12]

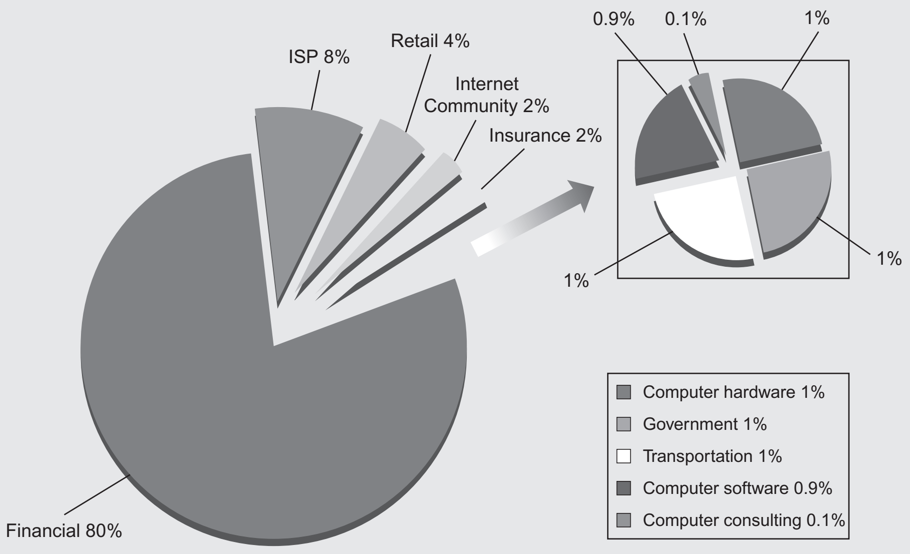

FIGURE 21.6 Unique brands phished by industry sectors, CSI/FBI report, 2008.[13]

having to deal with a security incident, especially if it leads to litigation, other factors could severely damage an organization's ability to operate, or damage the reputation of an organization beyond recovery. Some of the preliminary key findings from the 2008 CSI/FBI Security Report[11] (see Figure 21.8) include:

- Financial fraud cost organizations the most, with an average reported loss of close to $500,000.
- The second most expensive activity was dealing with bots within the network, reported to cost organizations an average of nearly $350,000.
- Virus incidents occurred most frequently, respondents said — at almost half (49%) of respondent organizations.

Some things to consider:

- How much would it cost your organization if your ecommerce Web server farm went down for 12 hours?
- What if your mainframe database that houses your reservation system was not accessible for an entire afternoon?

- What if your Web site was defaced and rerouted all your customers to a site infected with malicious Java scripts?
- Would any of these scenarios significantly impact your organization's bottom line?

2. PROTECTING MISSION-CRITICAL SYSTEMS

The IT core of any organization is its mission-critical systems. These are systems without which the mission of the organization, whether building aircraft carriers for the U.S. military or packaging Twinkies to deliver to food markets, could not operate. The major components to protecting these systems are detailed throughout this chapter; however, with special emphasis on the big picture an information security manager must keep in mind, there are some key components that are crucial for the success and continuity of any organization. These are information assurance, information risk management, defense in depth, and contingency planning.

Information Assurance

Information assurance is achieved when information and information systems are protected against attacks through the application of security services such as availability, integrity, authentication, confidentiality, and nonrepudiation. The application of these services should be based on the protect, detect, and react paradigm. This means that in addition to incorporating protection mechanisms, organizations need to expect attacks and include attack detection tools and procedures that allow them to react to and recover from these unexpected attacks.[16]

Information Risk Management

Risk is, in essence, the likelihood of something going wrong and damaging your organization or information assets. Due to the ramifications of such risk, an organization should try to reduce the risk to an acceptable level. This process is known as *information risk management*. Risk to an organization and its information assets, similar to threats, comes in many different forms. Some of the most common risks and/or threats are:

- *Physical damage.* Fire, water, vandalism, power loss and natural disasters.
- *Human interaction.* Accidental or intentional action or inaction that can disrupt productivity.
- *Equipment malfunctions.* Failure of systems and peripheral devices.
- *Internal or external attacks.* Hacking, cracking, and attacking.
- *Misuse of data.* Sharing trade secrets; fraud, espionage, and theft.
- *Loss of data.* Intentional or unintentional loss of information through destructive means.
- *Application error.* Computation errors, input errors, and buffer overflows.

The idea of risk management is that threats of any kind must be identified, classified, and evaluated to calculate their damage potential.[17] This is easier said than done.

Administrative, Technical, and Physical Controls

For example, administrative, technical, and physical controls, are as follows:

- Administrative controls consist of organizational policies and guidelines that help minimize the exposure of an organization. They provide a framework by which a business can manage and inform its people how they should conduct themselves while at the workplace and provide clear steps employees can take when they're confronted with a potentially risky situation. Some examples of administrative controls include the corporate security policy, password policy, hiring policies, and disciplinary policies that form the basis for the selection and implementation of logical and physical controls. Administrative controls are of paramount importance because technical and physical controls are manifestations of the administrative control policies that are in place.
- Technical controls use software and hardware resources to control access to information and computing systems, to help mitigate the potential for errors and blatant security policy violations. Examples of technical controls include passwords, network- and host-based firewalls, network intrusion detection systems, and access control lists and data encryption. Associated with technical controls is the *Principle of Least Privilege*, which requires that an individual, program, or system process is not granted any more access privileges than are necessary to perform the task.
- Physical controls monitor and protect the physical environment of the workplace and computing facilities. They also monitor and control access to and from such facilities. Separating the network and workplace into functional areas are also physical controls. An important physical control is also separation of duties, which ensures that an individual cannot complete a critical task by herself.

Risk Analysis

During risk analysis there are several units that can help measure risk. Before risk can be measured, though, the organization must identify the vulnerabilities and threats against its mission-critical systems in terms of business continuity. During risk analysis, an organization tries to evaluate the cost for each security control that helps mitigate the risk. If the control is cost effective relative to the exposure of the organization, then the control is put in place. The measure of risk can be determined as a product of threat, vulnerability, and asset values—in other words:

$$\text{Risk} = \text{Asset} \times \text{Threat} \times \text{Vulnerability}$$

There are two primary types of risk analysis: quantitative and qualitative. *Quantitative risk analysis* attempts to assign meaningful numbers to all elements of the risk analysis process. It is recommended for large, costly projects that require exact calculations. It is typically performed to examine the viability of a project's cost or time objectives. Quantitative risk analysis provides answers to three questions that cannot be addressed with deterministic risk and project management methodologies such as traditional cost estimating or project scheduling[18] :

- What's the probability of meeting the project objective, given all known risks?

17. Shon Harris, *All in One CISSP Certification Exam Guide 4th Edition*, McGraw Hill Companies

18. Lionel Galway, *Quantitative Risk Analysis for Project Management, A Critical Review*, WR-112-RC, February 2004, Rand.org Web site, http://www.rand.org/pubs/working_papers/2004/RAND_WR112.pdf

- How much could the overrun or delay be, and therefore how much contingency do we need for the organization's desired level of certainty?
- Where in the project is the most risk, given the model of the project and the totality of all identified and quantified risks?

Qualitative risk analysis does not assign numerical values but instead opts for general categorization by severity levels. Where little or no numerical data is available for a risk assessment, the qualitative approach is the most appropriate. The qualitative approach does not require heavy mathematics; instead, it thrives more on the people participating and their backgrounds. Qualitative analysis enables classification of risk that is determined by people's wide experience and knowledge captured within the process. Ultimately it is not an exact science, so the process will count on expert opinions for its base assumptions. The assessment process uses a structured and documented approach and agreed likelihood and consequence evaluation tables. It is also quite common to calculate risk as a single loss expectancy (SLE) or annual loss expectancy (ALE) by project or business function.

Defense in Depth

The principle of *defense in depth* is that layered security mechanisms increase security of a system as a whole. If an attack causes one security mechanism to fail, other mechanisms may still provide the necessary security to protect the system.[19] This is a process that involves people, technology, and operations as key components to its success; however, those are only part of the picture. These organizational layers are difficult to translate into specific technological layers of defenses, and they leave out areas such as security monitoring and metrics. Figure 21.9 shows a mind map that organizes the major categories from both the organizational and technical aspects of defense in depth and takes into account people, policies, monitoring, and security metrics.

Contingency Planning

Contingency planning is necessary in several ways for an organization to be sure it can withstand some sort of security breach or disaster. Among the important steps required to make sure an organization is protected and able to respond to a security breach or disaster are business impact analysis, incident response planning, disaster recovery planning, and business continuity planning. These contingency plans are interrelated in several ways and need to stay that way so that a response team can change from one to the other seamlessly if there is a need. Figure 21.10 shows the relationship between the four types of contingency plans with the major categories defined in each.

Business impact analysis must be performed in every organization to determine exactly which business process is deemed mission-critical and which processes would not seriously hamper business operations should they be unavailable for some time. An important part of a business impact analysis is the recovery strategy that is usually defined at the end of the process. If a thorough business impact analysis is performed, there should be a clear picture of the priority of each organization's highest-impact, therefore risky, business processes and assets as well as a clear strategy to recover from an interruption in one of these areas.[20]

An Incident Response (IR) Plan

It is a detailed set of processes and procedures that anticipate, detect, and mitigate the impact of an unexpected event that might compromise information resources and assets. Incident response plans are composed of six major phases:

1. *Preparation.* Planning and readying in the event of a security incident.
2. *Identification.* To identify a set of events that have some negative impact on the business and can be considered a security incident.
3. *Containment.* During this phase the security incident has been identified and action is required to mitigate its potential damage.
4. *Eradication.* After it's contained, the incident must be eradicated and studied to make sure it has been thoroughly removed from the system.
5. *Recovery.* Bringing the business and assets involved in the security incident back to normal operations.
6. *Lessons learned.* A thorough review of how the incident occurred and the actions taken to respond to it where the lessons learned get applied to future incidents.

When a threat becomes a valid attack, it is classified as an information security incident if[21] :

- It is directed against information assets
- It has a realistic chance of success
- It threatens the confidentiality, integrity, or availability of information assets

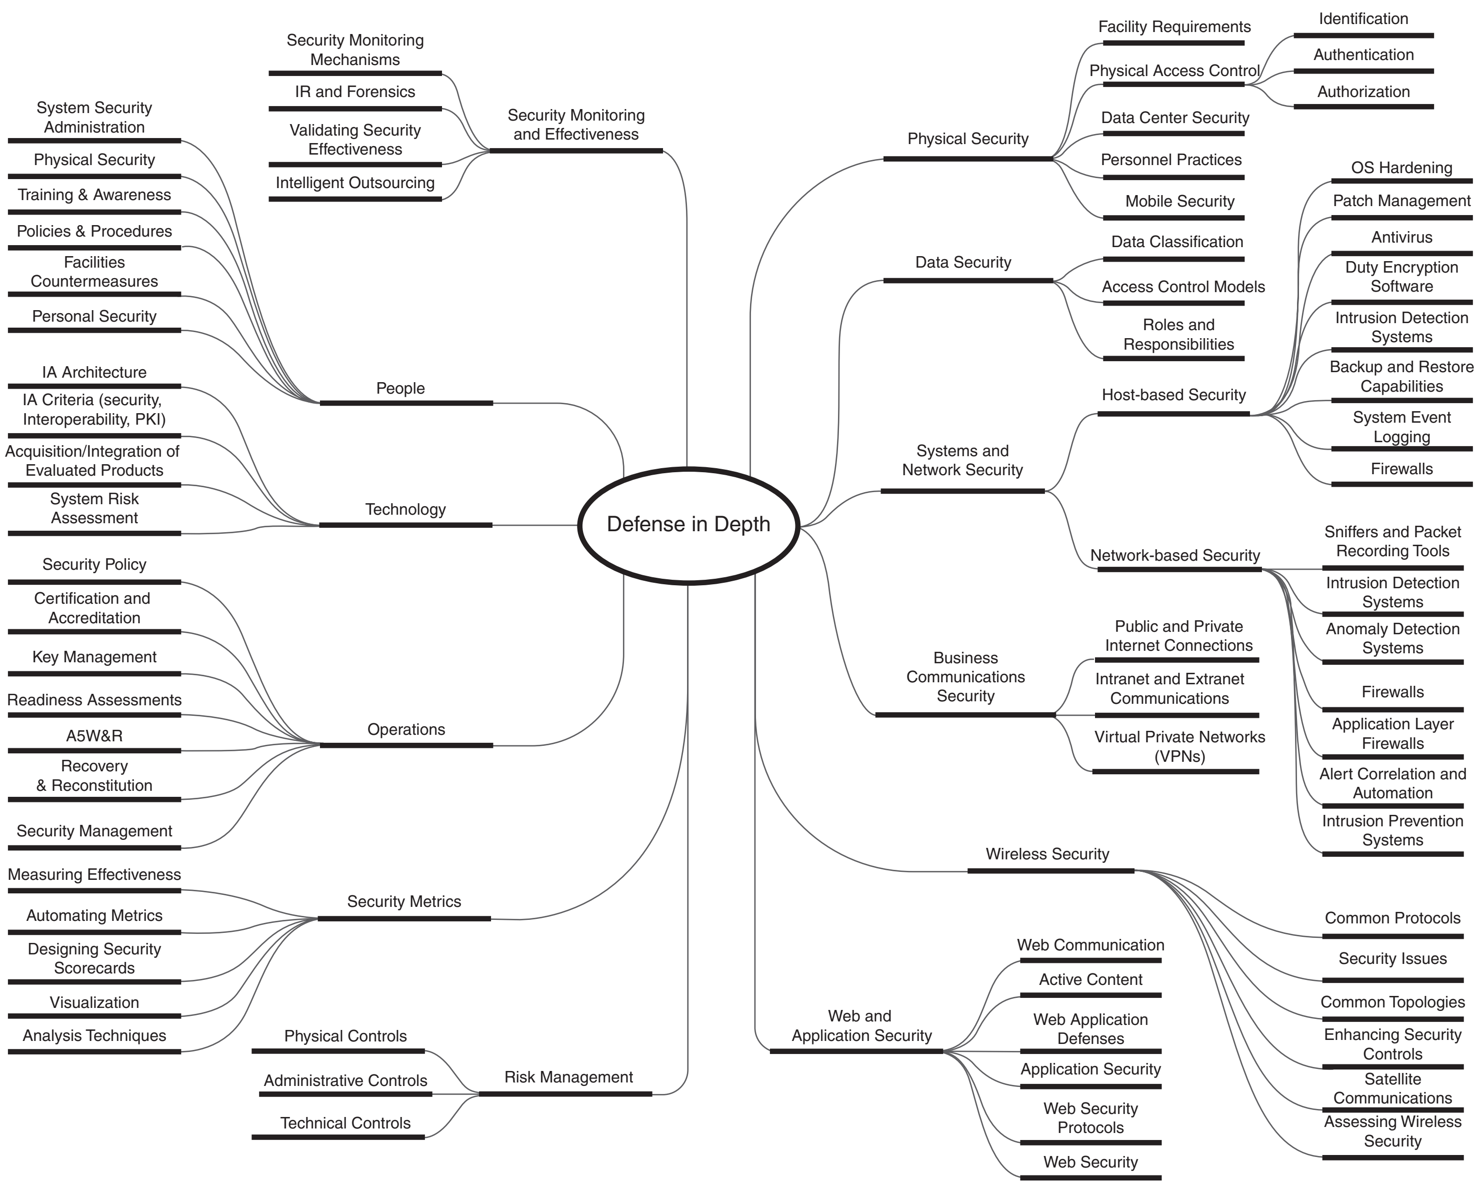

FIGURE 21.9 Defense-in-depth mind map.

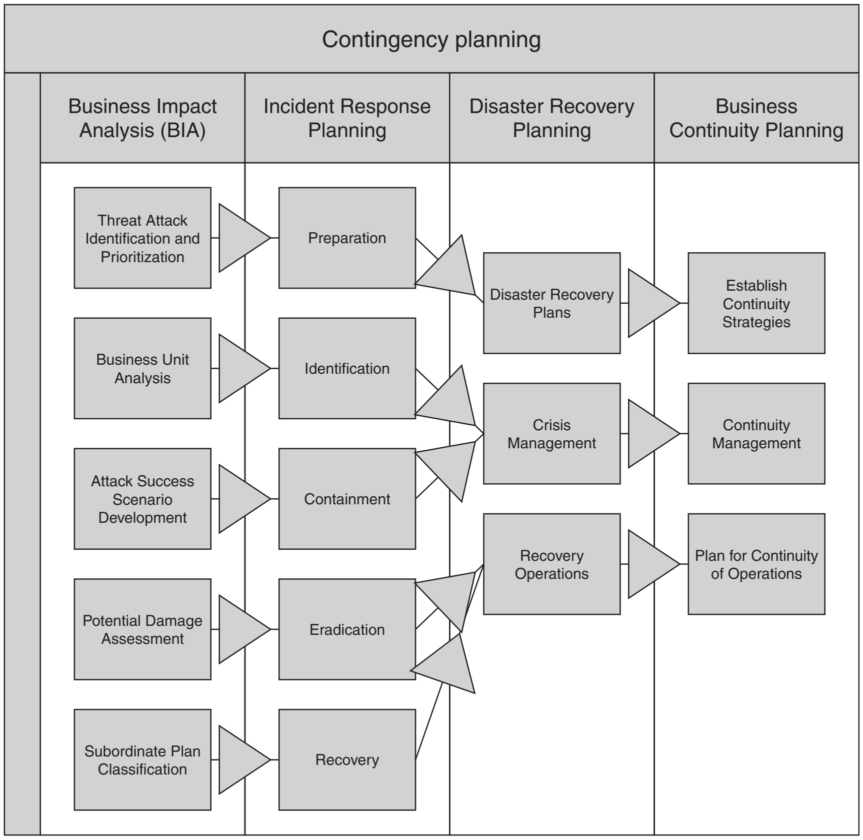

FIGURE 21.10 The relationship between the four types of contingency plans.

Business Continuity Planning (BCP)

It ensures that critical business functions can continue during a disaster and is most properly managed by the CEO of the organization. The BCP is usually activated and executed concurrently with *disaster recovery planning* (DRP) when needed and reestablishes critical functions at alternate sites (DRP focuses on reestablishment at the primary site). BCP relies on identification of critical business functions and the resources to support them using several continuity strategies, such as exclusive-use options like hot, warm, and cold sites or shared-use options like time-share, service bureaus, or mutual agreements.[22]

Disaster recovery planning is the preparation for and recovery from a disaster. Whether natural or manmade, it is an incident that has become a disaster because the organization is unable to contain or control its impact, or the level of damage or destruction from the incident is so severe that the organization is unable to recover quickly. The key role of DRP is defining how to reestablish operations at the site where the organization is usually located.[23] Key points in a properly designed DRP:

- Clear delegation of roles and responsibilities
- Execution of alert roster and notification of key personnel
- Clear establishment of priorities
- Documentation of the disaster
- Action steps to mitigate the impact
- Alternative implementations for various systems components
- DRP must be tested regularly

3. INFORMATION SECURITY FROM THE GROUND UP

The core concepts of information security management and protecting mission-critical systems have been explained. Now, how do you actually apply these concepts to your organization from the ground up? You literally start at the ground (physical) level and work yourself up to the top (application) level. This model can be applied to many IT frameworks, ranging from networking models such as OSI or TCP/IP stacks to operating systems or other problems such as organizational information security and protecting mission-critical systems.

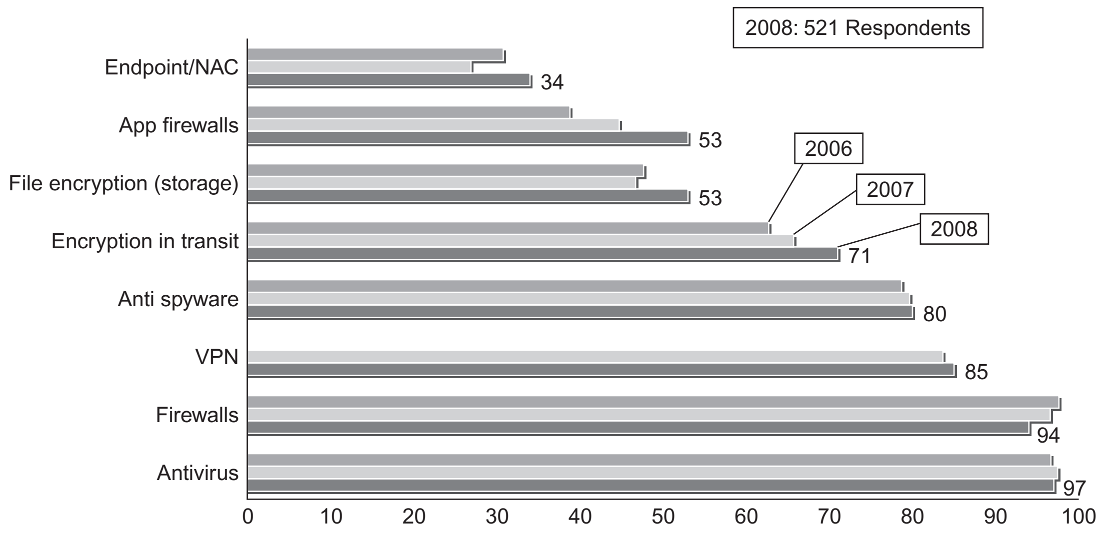

FIGURE 21.11 Security technologies used by organizations, CSI/FBI report, 2008.

There are many areas of security, all of which are interrelated. You can have an extremely hardened system running your ecommerce Web site and database; however, if physical access to the system is obtained by the wrong person, a simple yanking of the right power plug can be game over. In other words, to think that any of the following components is not important to the overall security of your organization is to provide malicious attackers the only thing they need to be successful — that is, the path of least resistance. The next parts of this chapter each contain an overview of the technologies (see Figure 21.11) and processes of which information security managers must be aware to successfully secure the assets of any organization:

- Physical security
- Data security
- Systems and network security
- Business communications security
- Wireless security
- Web and application security
- Security policies and procedures
- Security employee training and awareness

Physical Security

Physical security as defined earlier concerns itself with threats, risks, and countermeasures to protect facilities, hardware, data, media and personnel. Main topics include restricted areas, authorization models, intrusion detection, fire detection, and security guards. Therefore physical safeguards must be put in place to protect the organization from damaging consequences. The security rule defines physical safeguards as "physical measures, policies, and procedures to protect a covered entity's electronic information systems and related buildings and equipment, from natural and environmental hazards, and unauthorized intrusion."[24] A brief description of the baseline requirements to implement these safeguards at your facility follow.

Facility Requirements

Entering and accessing information systems to any degree within any organization must be controlled. What's more, it is necessary to understand what is allowed and what's not; if those parameters are clearly defied, the battle is half won. Not every building is a high-security facility, so it's understandable that some of the following items might not apply to your organization; however, there should be a good, clear reason as to why they don't. Sample questions and comments to consider:[25]

- Are policies and procedures developed and implemented that address allowing authorized and limiting unauthorized physical access to electronic information systems and the facility or facilities in which they are housed?
- Do the policies and procedures identify individuals (workforce members, business associates, contractors, etc.) with authorized access by title and/or job function?
- Do the policies and procedures specify the methods used to control physical access, such as door locks, electronic access control systems, security officers, or video monitoring?

24. 45 C.F.R. § 164.310 Physical safeguards, http://law.justia.com/us/cfr/title45/45-1.0.1.3.70.3.33.5.html

25. 45 C.F.R. § 164.310 Physical safeguards, http://law.justia.com/us/cfr/title45/45-1.0.1.3.70.3.33.5.html

The facility access controls standard has four implementation specifications[26] :

- *Contingency operations.* Establish (and implement as needed) procedures that allow facility access in support of restoration of lost data under the disaster recovery plan and emergency mode operations plan in the event of an emergency.
- *Facility security plan.* Implement policies and procedures to safeguard the facility and the equipment therein from unauthorized physical access, tampering, and theft.
- *Access control and validation procedures.* Implement procedures to control and validate a person's access to facilities based on her role or function, including visitor control and control of access to software programs for testing and revision.
- *Maintenance records.* Implement policies and procedures to document repairs and modifications to the physical components of a facility that are related to security (for example, hardware, walls, doors, and locks).

Administrative, Technical, and Physical Controls

Understanding what it takes to secure a facility is the first step in the process of identifying exactly what type of administrative, technical, and physical controls will be necessary for your particular organization. Translating the needs for security into tangible examples, here are some of the controls that can be put in place to enhance security:

- *Administrative controls.* These include human resources exercises for simulated emergencies such as fire drills or power outages as well as security awareness training and security policies.
- *Technical controls.* These include physical intrusion detection systems and access control equipment such as biometrics.
- *Physical controls.* These include video cameras, guarded gates, man traps, and car traps.

Data Security

Data security is at the core of what needs to be protected in terms of information security and mission-critical systems. Ultimately it is the data that the organization needs to protect in many cases, and usually data is exactly what perpetrators are after, whether trade secrets, customer information, or a database of Social Security numbers — the data is where it's at!

26. 45 C.F.R. § 164.310 Physical safeguards, http://law.justia.com/us/cfr/title45/45-1.0.1.3.70.3.33.5.html

To be able to properly classify and restrict data, the first thing to understand is how data is accessed. Data is accessed by a *subject*, whether that is a person, process, or another application, and what is accessed to retrieve the data is called an *object*. Think of an object as a cookie jar with valuable information in it, and only select subjects have the permissions necessary to dip their hands into the cookie jar and retrieve the data or information that they are looking for. Both subjects and objects can be a number of things acting in a network, depending on what action they are taking at any given moment, as shown in Figure 21.12.

Data Classification

Various *data classification* models are available for different environments. Some security models focus on the confidentiality of the data (such as Bell-La Padula) and use different classifications. For example, the U.S. military uses a model that goes from most confidential (Top Secret) to least confidential (Unclassified) to classify the data on any given system. On the other hand, most corporate entities prefer a model whereby they classify data by business unit (HR, Marketing, R & D . . .) or use terms such as Company Confidential to define items that should not be shared with the public. Other security models focus on the integrity of the data (for example, Bipa); yet others are expressed by mapping security policies to data classification (for example, Clark-Wilson). In every case there are areas that require special attention and clarification.

Access Control Models

Three main *access control models* are in use today: RBAC, DAC, and MAC. In Role-Based Access Control (RBAC), the job function of the individual determines the group he is assigned to and determines the level of access he can attain on certain data and systems. The level of access is usually defined by IT personnel in accordance with policies and procedures. In Discretionary Access Control (DAC), the end user or creator of the data object is allowed to define who can and who cannot access the data; this has become less popular in recent history. Mandatory Access Control (MAC) is more of a militant style of applying permissions, where permissions are the same across the board to all members of a certain level or class within the organization. The following are data security "need to knows":

- *Authentication versus authorization.* It's crucial to understand that simply because someone becomes authenticated does not mean that they are authorized to view certain data. There needs to be a means by which a person, after gaining access through authentication, is limited in the actions they are authorized to

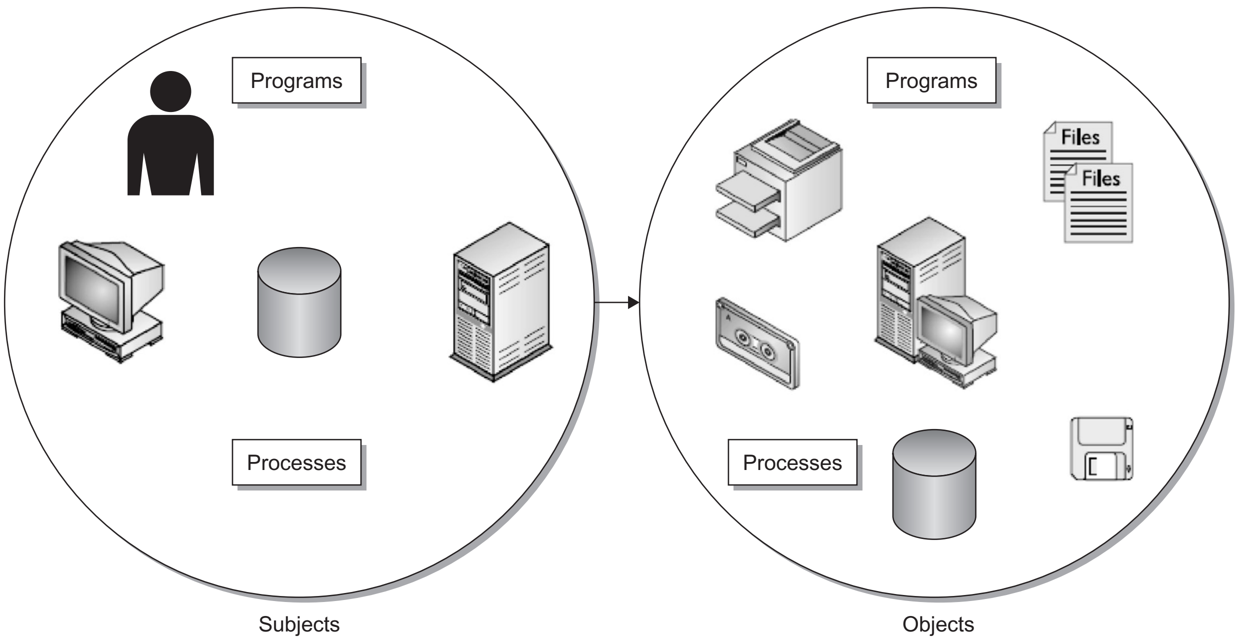

FIGURE 21.12 Subjects access objects.

perform on certain data (such as read-only permissions).

- *Protecting data with cryptography* is important for the security of both the organization and its customers. Usually the most important item that an organization needs to protect, aside from trade secrets, is its customers' personal data. If there is a security breach and the data that is stolen or compromised was previously encrypted, the organization can feel more secure in that the collateral damage to their reputation and customer base will be minimized.
- *Data leakage prevention and content management* is an up-and-coming area of data security that has proven extremely useful in preventing sensitive information from leaving an organization. With this relatively new technology, a security administrator can define the types of documents, and further define the content within those documents, that cannot leave the organization and quarantine them for inspection before they hit the public Internet.
- *Securing email systems* is one of the most important and overlooked areas of data security. With access to the mail server, an attacker can snoop through anyone's email, even the company CEO's! Password files, company confidential documents, and contacts for all address books are only some of the things that a compromised mail server can reveal about an organization, not to mention root/administrator access to a system in the internal network.

Systems and Network Security

Systems and network security[27] is at the core of information security. Though physical security is extremely important and a breach could render all your systems and network security safeguards useless, without hardened systems and networks, anyone from the comfort of her own living room can take over your network, access your confidential information, and disrupt your operations at will. Data classification and security are also quite important, if for nothing else to be sure that only those who need to access certain data can and those who do not need access cannot; however, that usually works well for people who play by the rules. In many cases when an attacker gains access to a system, the first order of business is escalation of privileges. This means that the attacker gets in as a regular user and attempts to find ways to gain administrator or root privileges. The following are brief descriptions of each of the components that make for a complete security infrastructure for all host systems and network connected assets.

Host-Based Security

The host system is the core of where data sits and is accessed, so it is therefore also the main target of many

27. "GSEC, GIAC Security Essentials Outline," SANS Institute, https://www.sans.org/training/description.php?tid = 672

intruders. Regardless of the operating system platform that is selected to run certain applications and databases, the principles of hardening systems are the same and apply to host systems as well as network devices, as we will see in the upcoming sections. Steps required to maintain host systems in as secure a state as possible are as follows:

1. *OS hardening.* Guidelines by which a base operating system goes through a series of checks to make sure no unnecessary exposures remain open and that security features are enabled where possible. There is a series of organizations that publish OS hardening Guides for various platforms of operating systems.
2. *Removing unnecessary services.* In any operating system there are usually services that are enabled but have no real business need. It is necessary to go through all the services of your main corporate image, on both the server side and client side, to determine which services are required and which would create a potential vulnerability if left enabled.
3. *Patch management.* All vendors release updates for known vulnerabilities on some kind of schedule. Part of host-based security is making sure that all required vendor patches, at both the operating system and the application level, are applied as quickly as business operations allow on some kind of regular schedule. There should also be an emergency patch procedure in case there is an outbreak and updates need to be pushed out of sequence.
4. *Antivirus.* Possibly more important than patches are antivirus definitions, specifically on desktop and mobile systems. Corporate antivirus software should be installed and updated frequently on all systems in the organization.
5. *Intrusion detection systems (IDSs).* Although many seem to think IDSs are a network security function, there are many good host-based IDS applications, both commercial and open source, that can significantly increase security and act as an early warning system for possibly malicious traffic and/or files for which the AV does not have a definition.
6. *Firewalls.* Host-based firewalls are not as popular as they once were because many big vendors such as Symantec, McAfee, and Checkpoint have moved to a host-based client application that houses all security functions in one. There is also another trend in the industry to move toward application-specific host-based firewalls like those specifically designed to run on a Web or database server, for example.
7. *Data encryption software.* One item often overlooked is encryption of data while it is at rest. Many solutions have recently come onto the market that offer the ability to encrypt sensitive data such as credit card and Social Security numbers that sit on your file server or inside the database server. This is a huge protection in the case of information theft or data leakage.
8. *Backup and restore capabilities.* Without the ability to back up and restore both servers and clients in a timely fashion, an issue that could be resolved in short order can quickly turn into a disaster. Backup procedures should be in place and restored on a regular basis to verify their integrity.
9. *System event logging.* Event logs are significant when you're attempting to investigate the root cause of an issue or incident. In many cases, logging is not turned on by default and needs to be enabled after the core installation of the host operating system. The OS hardening guidelines for your organization should require that logging be enabled.

Network-Based Security

The network is the communication highway for everything that happens between all the host systems. All data at one point or another passes over the wire and is potentially vulnerable to snooping or spying by the wrong person. The controls implemented on the network are similar in nature to those that can be applied to host systems; however, network-based security can be more easily classified into two main categories: detection and prevention. We will discuss security monitoring tools in another section; for now the main functions of network-based security are to either detect a potential incident based on a set of events or prevent a known attack.

Most network-based security devices can perform detect or protect functions in one of two ways: signature-based or anomaly-based. Signature-based detection or prevention is similar to AV signatures that look for known traits of a particular attack or malware. Anomaly-based systems can make decisions based on what is expected to be "normal" on the network or per a certain set of standards (for example, RFC), usually after a period of being installed in what is called "learning" or "monitor" mode.

Intrusion Detection

Intrusion detection is the process of monitoring the events occurring in a computer system or network and analyzing them for signs of possible incidents that are violations or imminent threats of violation of computer security policies, acceptable-use policies, or standard security practices. Incidents have many causes, such as malware (worms, spyware), attackers gaining unauthorized access to systems from the Internet, and authorized system users who misuse their privileges or attempt to gain additional

privileges for which they are not authorized.[28] The most common detection technologies and their security functions on the network are as follows:

- *Packet sniffing and recording tools.* These tools are used quite often by networking teams to troubleshoot connectivity issues; however, they can be a security professional's best friend during investigations and root-cause analysis. When properly deployed and maintained, a packet capture device on the network allows security professionals to reconstruct data and reverseengineer malware in a way that is simply not possible without a full packet capture of the communications.
- *Intrusion detection systems.* In these systems, appliances or servers monitor network traffic and run it through a rules engine to determine whether it is malicious according to its signature set. If the traffic is deemed malicious, an alert will fire and notify the monitoring system.
- *Anomaly detection systems.* Aside from the actual packet data traveling on the wire, there are also traffic trends that can be monitored on the switches and routers to determine whether unauthorized or anomalous activity is occurring. With Net-flow and S-flow data that can be sent to an appliance or server, aggregated traffic on the network can be analyzed and can alert a monitoring system if there is a problem. Anomaly detection systems are extremely useful when there is an attack for which the IDS does not have a signature or if there is some activity occurring that is suspicious.

Intrusion Prevention

Intrusion prevention is a system that allows for the active blocking of attacks while they are inline on the network, before they even get to the target host. There are many ways to prevent attacks or unwanted traffic from coming into your network, the most common of which is known as a firewall. Although a firewall is mentioned quite commonly and a lot of people know what a firewall is, there are several different types of controls that can be put in place in addition to a firewall that can seriously help protect the network. Here are the most common prevention technologies:

- *Firewalls.* The purpose of a firewall is to enforce an organization's security policy at the border of two networks. Typically most firewalls are deployed at the edge between the internal network and the Internet (if there is such a thing) and are configured to block (prevent) any traffic from going in or out that is not allowed by the corporate security policy. There are quite a few different levels of protection a firewall can provide, depending on the type of firewall that is deployed, such as these:
- *Packet filtering.* The most basic type of firewalls perform what is called *stateful packet filtering*, which means that they can remember which side initiated the connection, and rules (called access control lists, or ACLs) can be created based not only on IPs and ports but also depending on the state of the connection (meaning whether the traffic is going into or out of the network).
- *Proxies.* The main difference between proxies and stateful packet-filtering firewalls is that proxies have the ability to terminate and reestablish connections between two end hosts, acting as a proxy for all communications and adding a layer of security and functionality to the regular firewalls.
- *Application layer firewalls.* The app firewalls have become increasingly popular; they are designed to protect certain types of applications (Web or database) and can be configured to perform a level of blocking that is much more intuitive and granular, based not only on network information but also application-specific variables so that administrators can be much more precise in what they are blocking. In addition, app firewalls can typically be loaded with server-side SSL certificates, allowing the appliance to decrypt encrypted traffic, a huge benefit to a typical proxy or stateful firewall.
- *Intrusion prevention systems.* An intrusion prevention system (IPS) is software that has all the capabilities of an intrusion detection system and can also attempt to stop possible incidents using a set of conditions based on signatures or anomalies.

Business Communications Security

Businesses today tend to communicate with many other business entities, not only over the Internet but also through private networks or guest access connections directly to the organization's network, whether wired or wireless. Business partners and contractors conducting business communications obviously tend to need a higher level of access than public users but not as extensive as permanent employees, so how does an organization handle this phenomenon? External parties working on internal projects are also classed as business partners. Some general rules for users to maintain security control of external entities are shown in Figure 21.13.

28. Karen Scarfone and Peter Mell, NIST Special Publication 800–94: "Guide to Intrusion Detection and Prevention Systems (IDPS)," Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-94/SP800-94.pdf

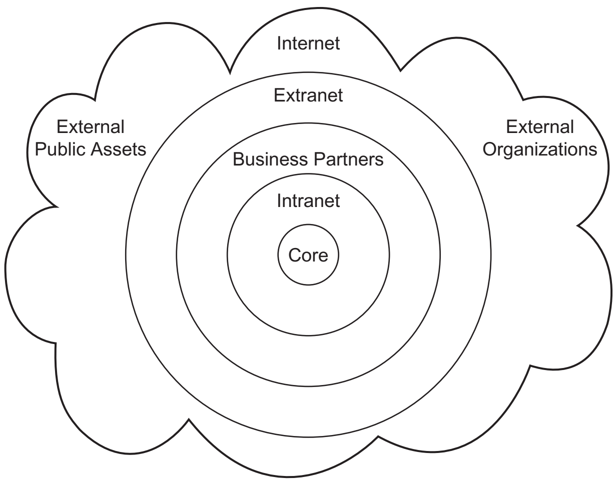

FIGURE 21.13 The business communications cloud.

General Rules for Self-Protection

The general rules for self-protection are as follows:

- Access to a user's own IT system must be protected in such a way that system settings (in the BIOS) can only be changed subject to authentication.
- System start must always be protected by requiring appropriate authentication (requesting the boot password). Exceptions to this rule can apply if:
- Automatic update procedures require this, and the system start can only take place from the built-in hard disk.
- The system is equipped for use by a number of persons with their individual user profiles, and system start can only take place from the built-in hard disk.
- Unauthorized access to in-house resources including data areas (shares, folders, mailboxes, calendar, etc.) must be prevented in line with their need for protection. In addition, the necessary authorizations for approved data access must be defined.
- Users are not permitted to operate resources without first defining any authorizations (such as no global sharing). This rule must be observed particularly by those users who are system managers of their own resources.
- Users of an IT system must lock the access links they have opened (for example, by enabling a screensaver or removing the chip card from the card reader), even during short periods of absence from their workstations.
- When work is over, all open access links must be properly closed or protected against system/data access (such as if extensive compilation runs need to take place during the night).
- Deputizing rules for access to the user's own system or data resources must be made in agreement with the manager and the acting employee.

Handling Protection Resources

The handling of protection resources are as follows:

- Employees must ensure that their protection resources cannot be subject to snooping while data required for authentication is being entered (e.g., password entry during login).
- Employees must store all protection resources and records in such a way that they cannot be subjected to snooping or stolen.
- Personal protection resources must never be made available to third parties.
- In the case of chip cards, SecurID tokens, or other protection resources requiring a PIN, the associated PIN (PIN letter) must be stored separately.
- Loss, theft, or disclosure of protection resources is to be reported immediately.
- Protection resources subject to loss, theft, or snooping must be disabled immediately.

Rules for Mobile IT Systems

In addition to the general rules for users, the following rules may also apply for mobile IT systems:

- Extended self-protection.
- A mobile IT system must be safeguarded against theft (that is, secured with a cable lock, locked away in a cupboard).
- The data from a mobile IT system using corporate proprietary information must be safeguarded as appropriate (e.g., encryption). In this connection, CERT rules in particular are to be observed.
- The software provided by the organization for system access control may only be used on the organization's own mobile IT systems.

Operation on Open Networks

Rules for operation on open networks are as follows:

- The mobile IT system must be operated in open network environments using a personal firewall.
- The configuration of the personal firewall must be in accordance with the corporate policy or, in the case of other personal firewall systems, must be subject to restrictive settings.
- A mobile IT system must be operated in an unprotected open network only for the duration of a secure access link to the organization's own network. The connection establishment for the secure access link

IEEE Standard or Amendment	Maximum Data Rate	Typical Range	Frequency Band	Comments
802.11	2 Mbps	50–100 meters	2.4 GHz	
802.11a	54 Mbps	50–100 meters	5 GHz	Not compatible with 802.11b
802.11b	11 Mbps	50–100 meters	2.4 GHz	Equipment based on 802.11b has been the dominant WLAN technology
802.11g	54 Mbps	50–100 meters	2.4 GHz	Backward compatible with 802.11b

FIGURE 21.14 IEEE Common Wireless Standards: NIST SP800−97.[30]

must be performed as soon as possible, at least within five minutes.
- Simultaneous operation on open networks (protected or unprotected) and the organization's own networks is forbidden at all times.
- Remote access to company internal resources must always be protected by means of strong authentication.
- For the protection of data being transferred via a remote access link, strong encryption must always be used.

Additional Business Communications Guidelines

Additional business communications guidelines should be defined for the following:

- External IT systems may not be connected directly to the intranet. Transmission of corporate proprietary data to external systems should be avoided wherever possible, and copies of confidential or strictly confidential data must never be created on external IT systems.
- Unauthorized access to public data areas (shares, folders, mailboxes, calendars, etc.) is to be prevented. The appropriate authentication checks and authorization requirements must be defined and the operation of resources without such requirements is not permitted (no global sharing).
- Remote data access operations must be effected using strong authentication and encryption, and managers must obtain permission from the owner of the resources to access.
- For secure remote maintenance by business partners, initialization of the remote maintenance must take place from an internal system, such as via an Internet connection protected by strong encryption. An employee must be present at the system concerned during the entire remote maintenance session to monitor the remote maintenance in accordance with the policy, and the date, nature, and extent of the remote maintenance must be logged at a minimum.

Wireless Security

Wireless networking enables devices with wireless capabilities to use information resources without being physically connected to a network. A wireless local area network (WLAN) is a group of wireless networking nodes within a limited geographic area that is capable of radio communications. WLANs are typically used by devices within a fairly limited range, such as an office building or building campus, and are usually implemented as extensions to existing wired local area networks to provide enhanced user mobility. Since the beginning of wireless networking, many standards and technologies have been developed for WLANs. One of the most active standards organizations that address wireless networking is the Institute of Electrical and Electronics Engineers (IEEE), as outlined in Figure 21.14.[29] Like other wireless technologies, WLANs typically need to support several security objectives. This is intended to be accomplished through a combination of security features built into the wireless networking standard. The most common security objectives for WLANs are as follows:

- *Access control.* Restrict the rights of devices or individuals to access a network or resources within a network.
- *Confidentiality.* Ensure that communication cannot be read by unauthorized parties.
- *Integrity.* Detect any intentional or unintentional changes to data that occur in transit.
- *Availability.* Ensure that devices and individuals can access a network and its resources whenever needed.

30. Sheila Frankel, Bernard Eydt, Les Owens, Karen Scarfone, NIST Special Publication 800−97: "Establishing Wireless Robust Security Networks: A Guide to IEEE 802.11i," Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-97/SP800-97.pdf

Access Control

Typically there are two means by which to validate the identities of wireless devices attempting to connect to a WLAN: open-system authentication and shared-key authentication. Neither of these alternatives is secure. The security provided by the default connection means is unacceptable; all it takes for a host to connect to your system is a Service Set Identifier (SSID) for the AP (which is a name that is broadcast in the clear) and, optionally, a MAC Address. The SSID was never intended to be used as an access control feature.

A MAC address is a unique 48-bit value that is permanently assigned to a particular wireless network interface. Many implementations of IEEE 802.11 allow administrators to specify a list of authorized MAC addresses; the AP will permit devices with those MAC addresses only to use the WLAN. This is known as *MAC address filtering*. However, since the MAC address is not encrypted, it is simple to intercept traffic and identify MAC addresses that are allowed past the MAC filter. Unfortunately, almost all WLAN adapters allow applications to set the MAC address, so it is relatively trivial to spoof a MAC address, meaning that attackers can easily gain unauthorized access. Additionally, the AP is not authenticated to the host by open-system authentication. Therefore, the host has to trust that it is communicating to the real AP and not an impostor AP that is using the same SSID. Therefore, open system authentication does not provide reasonable assurance of any identities and can easily be misused to gain unauthorized access to a WLAN or to trick users into connecting to a malicious WLAN.[31]

Confidentiality

The WEP protocol attempts some form of confidentiality by using the RC4 stream cipher algorithm to encrypt wireless communications. The standard for WEP specifies support for a 40-bit WEP key only; however, many vendors offer nonstandard extensions to WEP that support key lengths of up to 128 or even 256 bits. WEP also uses a 24-bit value known as an *initialization vector* (IV) as a seed value for initializing the cryptographic keystream. Ideally, larger key sizes translate to stronger protection, but the cryptographic technique used by WEP has known flaws that are not mitigated by longer keys. WEP is not the secure alternative you're looking for.

A possible threat against confidentiality is network traffic analysis. Eavesdroppers might be able to gain information by monitoring and noting which parties communicate at particular times. Also, analyzing traffic patterns can aid in determining the content of communications; for example, short bursts of activity might be caused by terminal emulation or instant messaging, whereas steady streams of activity might be generated by videoconferencing. More sophisticated analysis might be able to determine the operating systems in use based on the length of certain frames. Other than encrypting communications, IEEE 802.11, like most other network protocols, does not offer any features that might thwart network traffic analysis, such as adding random lengths of padding to messages or sending additional messages with randomly generated data.[32]

Integrity

Data integrity checking for messages transmitted between hosts and APs exists and is designed to reject any messages that have been changed in transit, such as by a manin-the-middle attack. WEP data integrity is based on a simple encrypted checksum — a 32-bit cyclic redundancy check (CRC-32) computed on each payload prior to transmission. The payload and checksum are encrypted using the RC4 keystream, and then transmitted. The receiver decrypts them, recomputes the checksum on the received payload, and compares it with the transmitted checksum. If the checksums are not the same, the transmitted data frame has been altered in transit, and the frame is discarded. Unfortunately, CRC-32 is subject to bit-flipping attacks, which means that an attacker knows which CRC-32 bits will change when message bits are altered. WEP attempts to counter this problem by encrypting the CRC-32 to produce an integrity check value (ICV). WEP's creators believed that an enciphered CRC-32 would be less subject to tampering. However, they did not realize that a property of stream ciphers such as WEP's RC4 is that bit flipping survives the encryption process — the same bits flip whether or not encryption is used. Therefore, the WEP ICV offers no additional protection against bit flipping.[33]

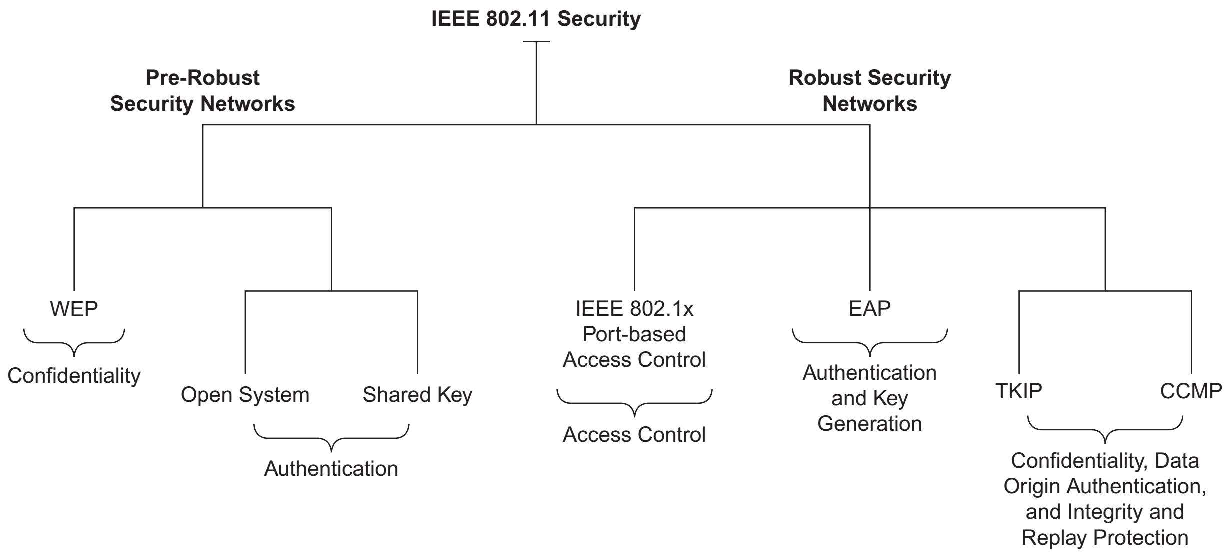

FIGURE 21.15 High-level taxonomy of the major pre-RSN and RSN security mechanisms.[35]

Availability

Individuals who do not have physical access to the WLAN infrastructure can cause a denial of service for the WLAN. One threat is known as jamming, which involves a device that emits electromagnetic energy on the WLAN's frequencies. The energy makes the frequencies unusable by the WLAN, causing a denial of service. Jamming can be performed intentionally by an attacker or unintentionally by a non-WLAN device transmitting on the same frequency. Another threat against availability is flooding, which involves an attacker sending large numbers of messages to an AP at such a high rate that the AP cannot process them, or other STAs cannot access the channel, causing a partial or total denial of service. These threats are difficult to counter in any radio-based communications; thus, the IEEE 802.11 standard does not provide any defense against jamming or flooding. Also, as described in Section 3.2.1, attackers can establish rogue APs; if STAs mistakenly attach to a rogue AP instead of a legitimate one, this could make the legitimate WLAN effectively unavailable to users. Although 802.11i protects data frames, it does not offer protection to control or management frames. An attacker can exploit the fact that management frames are not authenticated to deauthenticate a client or to disassociate a client from the network.[34]

Enhancing Security Controls

The IEEE 802.11i amendment allows for enhanced security features beyond WEP and the simple IEEE 802.11 shared-key challenge-response authentication. The amendment introduces the concepts of Robust Security Networks (RSNs) (see Figure 21.15) and Robust Security Network Associations (RSNAs). There are two RSN data confidentiality and integrity protocols defined in IEEE 802.11i—Temporal Key Integrity Protocol (TKIP) and Counter Mode with Cipher-Block Chaining Message Authentication Code Protocol (CCMP).

At a high level, RSN includes IEEE 802.1x port-based access control, key management techniques, and the TKIP and CCMP data confidentiality and integrity protocols. These protocols allow for the creation of several diverse types of security networks because of the numerous configuration options. RSN security is at the link level only, providing protection for traffic between a wireless host and its associated AP or between one wireless host and another. It does not provide end-to-end application-level security, such as between a host and an email or Web server, because communication between these entities requires more than just one link. For infrastructure mode, additional measures need to be taken to provide end-to-end security.

34. Sheila Frankel, Bernard Eydt, Les Owens Karen, Scarfone, NIST Special Publication 800−97: "Establishing Wireless Robust Security Networks: A Guide to IEEE 802.11i," Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-97/SP800-97.pdf

35. Sheila Frankel, Bernard Eydt, Les Owens Karen, Scarfone, NIST Special Publication 800−97: "Establishing Wireless Robust Security Networks: A Guide to IEEE 802.11i," Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-97/SP800-97.pdf

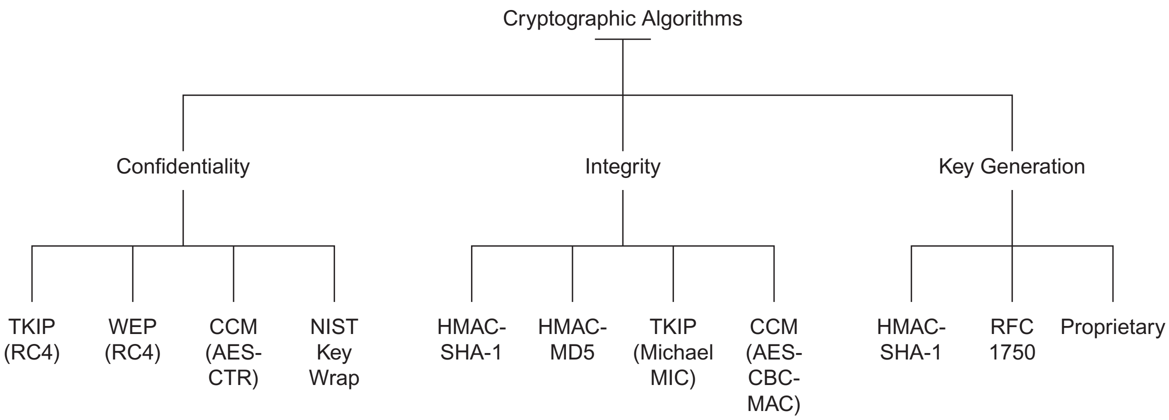

FIGURE 21.16 Taxonomy of the cryptographic algorithms included in the IEEE 802.11 standard.[36]

The IEEE 802.11i amendment defines an RSN as a wireless network that allows the creation of RSN Associations (RSNAs) only. An RSNA is a security relationship established by the IEEE 802.11i 4-Way Handshake. The 4-Way Handshake validates that the parties to the protocol instance possess a pairwise master key (PMK), synchronize the installation of temporal keys, and confirm the selection of cipher suites. The PMK is the cornerstone of a number of security features absent from WEP. Complete robust security is considered possible only when all devices in the network use RSNAs. In practice, some networks have a mix of RSNAs and non-RSNA connections. A network that allows the creation of both pre-RSN associations (pre-RSNA) and RSNAs is referred to as a Transition Security Network (TSN). A TSN is intended to be an interim means to provide connectivity while an organization migrates to networks based exclusively on RSNAs. RSNAs enable the following security features for IEEE 802.11 WLANs:

- Enhanced user authentication mechanisms
- Cryptographic key management
- Data confidentiality
- Data origin authentication and integrity
- Replay protection

An RSNA relies on IEEE 802.1x to provide an authentication framework. To achieve the robust security of RSNAs, the designers of the IEEE 802.11i amendment used numerous mature cryptographic algorithms and techniques. These algorithms can be categorized as being used for confidentiality, integrity (and data origin authentication), or key generation. All the algorithms specifically referenced in the IEEE 802.11 standard (see Figure 21.16) are symmetric algorithms, which use the same key for two different steps of the algorithm, such as encryption and decryption.

TKIP is a cipher suite for enhancing WEP on pre-RSN hardware without causing significant performance degradation. TKIP works within the processing constraints of first-generation hosts and APs and therefore enables increased security without requiring hardware replacement. TKIP provides the following fundamental security features for IEEE 802.11 WLANs:

- Confidentiality protection using the RC4 algorithm[38]
- Integrity protection against several types of attacks[39] using the Michael message digest algorithm (through generation of a message integrity code [MIC])[40]
- Replay prevention through a frame-sequencing technique
- Use of a new encryption key for each frame to prevent attacks, such as the Fluhrer-Mantin-Shamir (FMS) attack, which can compromise WEP-based WLANs[41]
- Implementation of countermeasures whenever the STA or AP encounters a frame with a MIC error, which is a strong indication of an active attack

Web and Application Security

Web and application security has come to center stage recently because Web sites and other public-facing applications have had so many vulnerabilities reported that it is often trivial to find some part of the application that is vulnerable to one of the many exploits out there. When an attacker compromises a system at the application level, often it is too trivial to take advantage of all the capabilities said application has to offer, including querying the back-end database or accessing proprietary information. In the past it was not necessary to implement security during the development phase of an application, and since most security professionals are not programmers, that

36. Sheila Frankel, Bernard Eydt, Les Owens, Karen Scarfone, NIST Special Publication 800–97: "Establishing Wireless Robust Security Networks: A Guide to IEEE 802.11i," Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-97/SP800-97.pdf

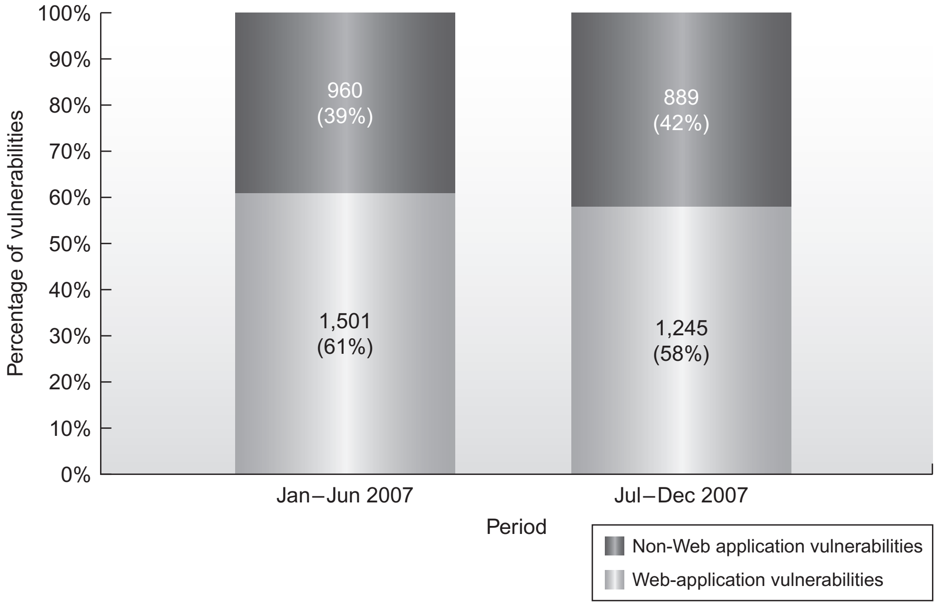

FIGURE 21.17 Symantec Web application vulnerabilities by share.

worked out just fine; however, due to factors such as rushing software releases and a certain level of complacency where end users expect buggy software and apply patches, the trend of inserting security earlier in the development process is catching steam.

Web Security

Web security is unique to every environment; any application and service that the organization wants to deliver to the customer will have its own way of performing transactions. Static Web sites with little content or searchable areas of course pose the least risk, but they also offer the least functionality. Who wants a Web site they can't sell anything from? Implementing something like a shopping cart or content delivery on your site opens up new, unexpected aspects of Web security. Among the things that need to be considered are whether it is worth developing the application in-house or buying one off the shelf and rely on someone else for the maintenance ad patching. With some of these thoughts in mind, here are some of the biggest threats associated with having a public-facing Web site:

- Vandalism
- Financial fraud
- Privileged access
- Theft of transaction information
- Theft of intellectual property
- Denial-of-service (DoS) attacks
- Input validation errors
- Path or directory traversal
- Unicode encoding
- URL encoding

Some Web application defenses that can be implemented have already been discussed; they include:

- Web application firewalls
- Intrusion prevention systems
- SYN proxies on the firewall

Application Security

An integrated approach to application security (see Figure 21.17) in the organization is required for successful deployment and secure maintenance of all applications. A corporate initiative to define, promote, assure, and measure the security of critical business applications would greatly enhance an organization's overall security. Some of the biggest obstacles, as mentioned in the previous section, are that security professionals are not typically developers, so this means that often application security is left to IT or R & D personnel, which can lead to gaping holes. Components of an application security program consist of[37]:

- *People.* Security architects, managers, technical leads, developers and testers.
- *Policy.* Integrate security steps into your SDLC and ADLC; have security baked in, not bolted on. Find security issues early so that they are easier and cheaper to fix. Measure compliance; are the processes working? Inventory and categorize your applications.

37. "AppSec2005DC-Anthony Canike-Enterprise AppSec Program PowerPoint Presentation," OWASP, http://www.owasp.org/index.php/Image:AppSec2005DC-Anthony_Canike-Enterprise_AppSec_Program.ppt

- *Standards*. Which controls are necessary, and when and why? Use standard methods to implement each control. Provide references on how to implement and define requirements.
- *Assessments*. Security architecture/design reviews, security code reviews, application vulnerability tests, risk acceptance review, external penetration test of production applications, white-box philosophy. Look inside the application, and use all the advantages you have such as past reviews, design documents, code, logs, interviews, and so on. Attackers have advantages over you; don't tie your hands.
- *Training*. Take awareness and training seriously. All developers should be performing their own input validation in their code and need to be made aware of the security risks involved in sending unsecure code into production.

Security Policies and Procedures

A quality information security program begins and ends with the correct information security policy (see Figure 21.18). Policies are the least expensive means of control and often the most difficult to implement. An information security policy is a plan that influences and determines the actions taken by employees who are presented with a policy decision regarding information systems. Other components related to a security policy are practices, procedures, and guidelines, which attempt to explain in more detail the actions that are to be taken by employees in any given situation. For policies to be effective, they must be properly disseminated, read, understood, and agreed to by all employees as well as backed by upper management. Without upper management support, a security policy is bound to fail. Most information security policies should contain at least:

- An overview of the corporate philosophy on security

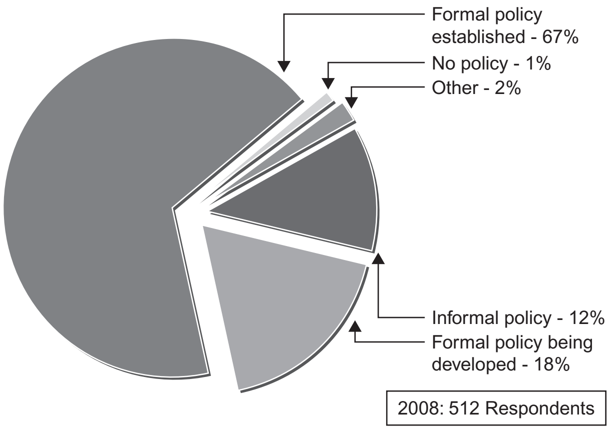

FIGURE 21.18 Information security policy within your organization, CSI/FBI report, 2008.

- Information about roles and responsibilities for security shared by all members of the organization
- Statement of purpose
- Information technology elements needed to define certain controls or decisions
- The organization's security responsibilities defining the security organization structure
- References to IT standards and guidelines, such as Government Policies and Guidelines, FISMA, http://iase.disa.mil/policy-guidance/index.html#FISMA and NIST Special Publications (800 Series), and http://csrc.nist.gov/publications/PubsSPs.html.

Some basic rules must be followed when you're shaping a policy:

- Never conflict with the local or federal law.
- Your policy should be able to stand up in court.
- It must be properly supported and administered by management.
- It should contribute to the success of the organization.
- It should involve end users of information systems from the beginning.

Security Employee Training and Awareness

The Security Employee Training and Awareness (SETA) program is a critical component of the information security program. It is the vehicle for disseminating security information that the workforce, including managers, need to do their jobs. In terms of the total security solution, the importance of the workforce in achieving information security goals and the importance of training as a countermeasure cannot be overstated. Establishing and maintaining a robust and relevant information security awareness and training program as part of the overall information security program is the primary conduit for providing employees with the information and tools needed to protect an agency's vital information resources. These programs will ensure that personnel at all levels of the organization understand their information security responsibilities to properly use and protect the information and resources entrusted to them. Agencies that continually train their workforces in organizational security policy and role-based security responsibilities will have a higher rate of success in protecting information.[38]

As cited in audit reports, periodicals, and conference presentations, people are arguably the weakest element in the security formula that is used to secure systems and networks. The people factor, not technology, is a critical one

38. Pauline Bowen, Joan Hash and Mark Wilson, NIST Special Publication 800−100: Information Security Handbook: A Guide for Managers. Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-100/SP800-100-Mar07-2007.pdf

	Awareness	Training	Education
Attribute	"What"	"How"	"Why"
Level	Information	Knowledge	Insight
Objective	Recognition	Skill	Understanding
Teaching Method	Media Videos Newsletters Posters, etc.	Practical Instruction Lecture Case study workshop Hands-on practice	Theoretical Instruction Discussion Seminar Background reading
Test Measure	True/False Multiple Choice (identify learning)	Problem Solving (apply learning)	Essay (interpret learning)
Impact Timeframe	Short-term	Intermediate	Long-term

FIGURE 21.19 Matrix of security teaching methods and measures that can be implemented.

that is often overlooked in the security equation. It is for this reason that the Federal Information Security Management Act (FISMA) and the Office of Personnel Management (OPM) have mandated that more and better attention must be devoted to awareness activities and role-based training, since they are the only security controls that can minimize the inherent risk that results from the people who use, manage, operate, and maintain information systems and networks. Robust and enterprisewide awareness and training programs are needed to address this growing concern.[39]

The Ten Commandments of SETA

The Ten Commandments of SETA consist of the following:

1. Information security is a people, rather than a technical, issue.
2. If you want them to understand, speak their language.
3. If they cannot see it, they will not learn it.
4. Make your point so that you can identify it and so can they.
5. Never lose your sense of humor.
6. Make your point, support it, and conclude it.
7. Always let the recipients know how the behavior that you request will affect them.
8. Ride the tame horses.
9. Formalize your training methodology.
10. Always be timely, even if it means slipping schedules to include urgent information.

39. Pauline Bowen, Joan Hash and Mark Wilson, NIST Special Publication 800−100: Information Security Handbook: A Guide for Managers. Recommendations of the National Institute of Standards and Technology, http://csrc.nist.gov/publications/nistpubs/800-100/SP800-100-Mar07-2007.pdf

Depending on the level of targeted groups within the organization, the goal is first awareness, then training, and eventually the education of all users as to what is acceptable security. Figure 21.19 shows a matrix of teaching methods and measures that can be implemented at each level.

Targeting the right people and providing the right information are crucial when you're developing a security awareness program. Therefore, some of the items that must be kept in mind are focusing on people, not so much on technologies; refraining from using technical jargon; and using every available venue, such as newsletters or memos, online demonstrations, and in-person classroom sessions. By not overloading users and helping them understand their roles in information security, you can establish a program that is effective, identifies target audiences, and defines program scope, goals, and objectives. Figure 21.20 presents a snapshot according to the 2008 CSI/FBI Report, showing where the SETA program stands in 460 different U.S. organizations.

4. SECURITY MONITORING AND EFFECTIVENESS

Security monitoring and effectiveness are the next evolutions to a constant presence of security-aware personnel who actively monitor and research events in real time. A substantial number of suspicious events occur within most enterprise networks and computer systems every day and go completely undetected. Only with an effective security monitoring strategy, an incident response plan, and security validation and metrics in place will an optimal level of security be attained. The idea is to automate and correlate as much as possible between both events and vulnerabilities

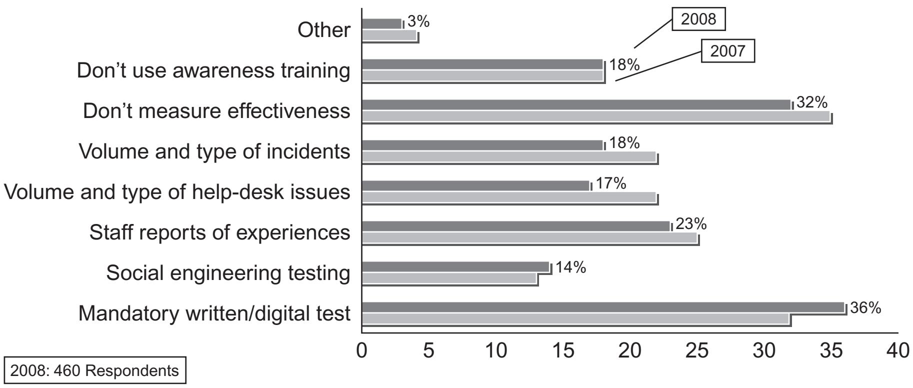

FIGURE 21.20 Awareness training metrics.

and to build intelligence into security tools so that they alert you if a known bad set of events has occurred or a known vulnerability is actually being attacked.

To come full circle; You need to define a security monitoring and log management strategy, an integrated incident response plan, validation, and penetration exercises against security controls and security metrics to help measure whether there has been improvement in your organization's handling of these issues.

Security Monitoring Mechanisms

Security monitoring involves real-time or near-real-time monitoring of events and activities happening on all your organization's important systems at all times. To properly monitor an organization for technical events that can lead to an incident or an investigation, usually an organization uses a security information and event management (SIEM) and/or log management tool. These tools are used by security analysts and managers to filter through tons of event data and to identify and focus on only the most interesting events.

Understanding the regulatory and forensic impact of event and alert data in any given enterprise takes planning and a thorough understanding of the quantity of data the system will be required to handle (see checklist: "An Agenda For Action When Implementing A Critical Security Mechanism"). The better logs can be stored,

An Agenda for Action when Implementing a Critical Security Mechanism

Without a solid log management strategy, it becomes nearly impossible to have the necessary data to perform a forensic investigation; and, without monitoring tools identifying threats and responding to attacks against confidentiality, integrity, or availability, it becomes much more difficult. For a network to be compliant and an incident response or forensics investigation to be successful, it is critical that a mechanism be in place to do the following (check all tasks completed):

_____**1.** Securely acquire and store raw log data for as long as possible from as many disparate devices as possible while providing search and restore capabilities of these logs for analysis.

_____**2.** Monitor interesting events coming from all important devices, systems, and applications in as near real time as possible.

_____**3.** Run regular vulnerability scans on your hosts and devices; and, correlate these vulnerabilities to intrusion detection alerts or other interesting events, identifying high-priority attacks as they happen, and minimizing false positives. SIEM and log management solutions in general can assist in security information monitoring (see Figure 21.21); as well as, regulatory compliance and incident response.

_____**4.** Aggregate and normalize event data from unrelated network devices, security devices, and application servers into usable information.

_____**5.** Analyze and correlate information from various sources such as vulnerability scanners, IDS/IPS, firewalls, servers, and so on, to identify attacks as soon as possible and help respond to intrusions more quickly.

_____**6.** Conduct network forensic analysis on historical or real-time events through visualization and replay of events.

_____**7.** Create customized reports for better visualization of your organizational security posture.

_____**8.** Increase the value and performance of existing security devices by providing a consolidated event management and analysis platform.

_____**9.** Improve the effectiveness and help focus IT risk management personnel on the events that are important.

_____**10.** Meet regulatory compliance and forensics requirements by securely storing all event data on a network for long-term retention and enabling instant accessibility to archived data.

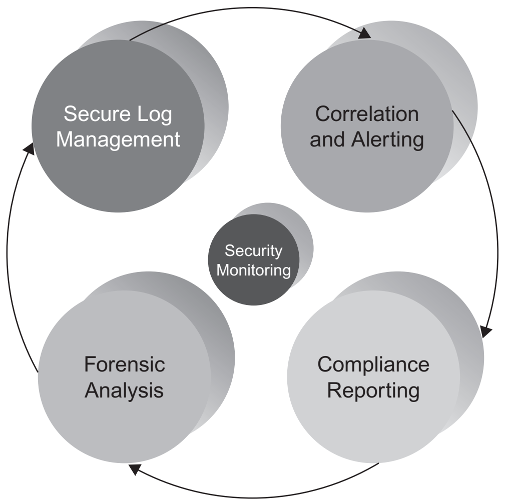

FIGURE 21.21 Security monitoring.

understood, and correlated, the better the possibility of detecting an incident in time for mitigation. In this case, what you don't know *will* hurt you. Responding to incidents, identifying anomalous or unauthorized behavior, and securing intellectual property has never been more important.

Incidence Response and Forensic Investigations

Network forensic investigation is the investigation and analysis of all the packets and events generated on any given network in hope of identifying the proverbial needle in a haystack. Tightly related is incident response, which entails acting in a timely manner to an identified anomaly or attack across the system. To be successful, both network investigations and incident response rely heavily on proper event and log management techniques. Before an incident can be responded to there is the challenge of determining whether an event is a routine system event or an actual incident. This requires that there be some framework for incident classification (the process of examining a possible incident and determining whether or not it requires a reaction). Initial reports from end users, intrusion detection systems, host- and network-based malware detection software, and systems administrators are all ways to track and detect incident candidates.[40]

As mentioned in earlier sections, the phases of an incident usually unfold in the following order: preparation, identification (detection), containment, eradication, recovery and lessons learned. The preparation phase requires detailed understanding of information systems and the threats they face; so to perform proper planning an organization must develop predefined responses that guide users through the steps needed to properly respond to an incident. Predefining incident responses enables rapid reaction without confusion or wasted time and effort, which can be crucial for the success of an incident response. Identification occurs once an actual incident has been confirmed and properly classified as an incident that requires action. At that point the IR team moves from identification to containment. In the containment phase, a number of action steps are taken by the IR team and others. These steps to respond to an incident must occur quickly and may occur concurrently, including notification of key personnel, the assignment of tasks, and documentation of the incident. Containment strategies focus on two tasks: first, stopping the incident from getting any worse, and second, recovering control of the system if it has been hijacked.

Once the incident has been contained and system control regained, eradication can begin, and the IR team must assess the full extent of damage to determine what must be done to restore the system. Immediate determination of the scope of the breach of confidentiality, integrity, and availability of information and information assets is called *incident damage assessment*. Those who document the damage must be trained to collect and preserve evidence in case the incident is part of a crime investigation or results in legal action.

At the moment that the extent of the damage has been determined, the recovery process begins to identify and resolve vulnerabilities that allowed the incident to occur in the first place. The IR team must address the issues found and determine whether they need to install and/or replace/upgrade the safeguards that failed to stop or limit the incident or were missing from system in the first place. Finally, a discussion of lessons learned should always be conducted to prevent future similar incidents from occurring and review what could have been done differently.[41]

Validating Security Effectiveness

The process of validating security effectiveness comprises making sure that the security controls that you have put in place are working as expected and that they are truly mitigating the risks they claim to be mitigating. There is no way to be sure that your network is not vulnerable to something if you haven't validated it yourself. Ensuring that the information security policy addresses your organizational needs and assessing compliance with your security policy across

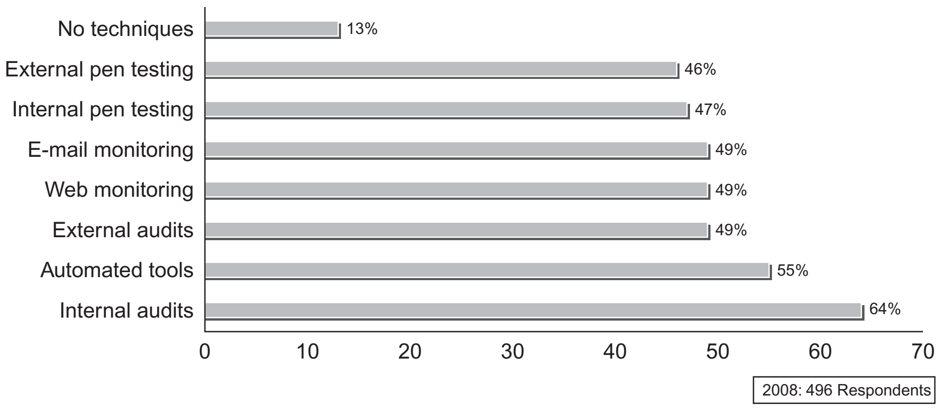

FIGURE 21.22 Security validation techniques, CSI/FBI survey, 2008.

all systems, assets, applications, and people is the only way to have a concrete means of validation.

Here are some areas where actual validation should be performed — in other words, these are areas where assigned IT personnel should go with policy in hand, log in, and verify the settings and reports before the auditors do:

- Verifying operating system settings
- Reviewing security device configuration and management
- Establishing ongoing security tasks
- Maintaining physical security
- Auditing security logs
- Creating an approved product list
- Reviewing encryption strength
- Providing documentation and change control

Vulnerability Assessments and Penetration Tests

Validating security (see Figure 21.22) with internal as well as external vulnerability assessments and penetration tests is a good way to measure an increase or decrease in overall security, especially if similar assessments are conducted on a regular basis. There are several ways to test security of applications, hosts, and network devices. With a vulnerability assessment, usually limited scanning tools or just one scanning tool is used to determine vulnerabilities that exist in the target system. Then a report is created and the manager reviews a holistic picture of security. With authorized penetration tests it's a little different. In that case the data owner is allowing someone to use just about any means within reason (in other words, many different tools and techniques) to gain access to the system or information. A successful penetration test does not provide the remediation avenues that a vulnerability assessment does; rather, it is a good test of how difficult it would be for someone to truly gain access if he were trying.

5. SUMMARY

This chapter emphasized how IT managers are expected to develop, document, and implement an organization-wide program to provide information security essentials for protecting mission-critical systems that support the operations and assets of the organization. An effective information security program should include:

- Periodic assessments of risk, including the magnitude of harm that could result from the unauthorized access, use, disclosure, disruption, modification, or destruction of information and information systems that support the operations and assets of the organization.
- Policies and procedures that are based on risk assessments, cost-effectively reduce information security risks to an acceptable level, and ensure that information security is addressed throughout the life cycle of each organizational information system.
- Subordinate plans for providing adequate information security for networks, facilities, information systems, or groups of information systems, as appropriate.
- Security awareness training to inform personnel (including users of information systems that support the operations and assets of the organization) of the information security risks associated with their activities and their responsibilities in complying with organizational policies and procedures designed to reduce these risks.
- Periodic testing and evaluation of the effectiveness of information security policies, procedures, practices, and security controls to be performed with a frequency depending on risk, but no less than annually.
- A process for planning, implementing, evaluating, and documenting remedial actions to address any deficiencies in the information security policies, procedures, and practices of the organization.
- Procedures for detecting, reporting, and responding to security incidents.

- Plans and procedures to ensure continuity of operations for information systems that support the operations and assets of the organization.

In other words, IT managers must be prepared to:

- Plan for security.
- Ensure that appropriate officials are assigned security responsibility.
- Periodically review the security controls in their information systems.
- Authorize system processing prior to operations and, periodically, thereafter.

The preceding management responsibilities presume that responsible IT managers understand the risks and other factors that could adversely affect their missions. Moreover, these managers must understand the current status of their security programs and the security controls planned or in place to protect their information and information systems in order to make informed judgments and investments that appropriately mitigate risk to an acceptable level. The ultimate objective is to conduct the day-to-day operations of the organization and to accomplish the organization's mission critical systems with adequate security, or security commensurate with risk, including the magnitude of harm resulting from the unauthorized access, use, disclosure, disruption, modification, or destruction of information.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Information security management as a field is ever decreasing in demand and responsibility because most organizations spend increasingly larger percentages of their IT budgets in attempting to manage risk and mitigate intrusions, not to mention the trend in many enterprises of moving all IT operations to an Internet-connected infrastructure, known as enterprise cloud computing.
2. True or False? Information security is a business problem in the sense that the entire organization must frame and solve security problems based on its own strategic drivers, not solely on technical controls aimed to mitigate one type of attack.
3. True or False? In defining required skills for information security managers, the ISC has arrived at an agreement on ten domains of information security that is known as the *Common Body of Knowledge* (CBK).
4. True or False? Threats to information systems come in many flavors, some with malicious intent, others with supernatural powers or expected surprises.
5. True or False? Threats are exploited with a variety of attacks, some technical, others not so much.

Multiple Choice

1. The art of manipulating people into performing actions or divulging confidential information, is known as:
   A. Malware
   B. Industrial espionage
   C. Social engineering
   D. Spam
   E. Phishing
2. What describes activities such as theft of trade secrets, bribery, blackmail, and technological surveillance as well as spying on commercial organizations and sometimes governments?
   A. Spam
   B. Phishing
   C. Hoaxes
   D. Industrial espionage
   E. Denial-of-service
3. What is the abuse of electronic messaging systems to indiscriminately send unsolicited bulk messages, many of which contain hoaxes or other undesirable contents such as links to phishing sites?
   A. Spamming
   B. Phishing
   C. Hoaxes
   D. Distributed denial-of-service
   E. All of the Above
4. What is the criminally fraudulent process of attempting to acquire sensitive information such as usernames, passwords, and credit-card details by masquerading as a trustworthy entity in an electronic communication?
   A. Splicing
   B. Phishing
   C. Bending
   D. FSO
   E. Cabling
5. What requires that an individual, program, or system process is not granted any more access privileges than are necessary to perform the task?
   A. Administrative controls
   B. Principle of Least Privilege
   C. Technical controls
   D. Physical controls
   E. Risk analysis

EXERCISE

Security Management Systems

James T. Harmening
Computer Bits, Inc.

1. SECURITY MANAGEMENT SYSTEM STANDARDS

To give organizations a starting point to develop their own security management systems, the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC) have developed a family of standards known as the Information Security Management System 27000 Family of Standards. This group of standards, starting with ISO/IEC 27001, gives organizations the ability to certify their security management systems. For more details see WWW.ISO.ORG. As an alternative some organizations are following the SANS 20 Critical Security Controls (http://www.sans.org/critical-security-controls/) set of twenty critical security controls that lead you through a twenty step audit process for your organization.

The ISO/IEC-27001 certification process takes place in several stages. The first stage is an audit of all documentation and policies that currently exist for a system. The documentation is usually based directly on the requirements of the standard, but it does not have to be. Organizations can come up with their own sets of standards, as long as all aspects of the standard are covered. The second stage actually tests the effectiveness of the existing policies. The third stage is a reassessment of the organization to make sure it still meets the requirements. This third stage keeps organizations up to date over time as standards for security management systems change. This certification process is based on a Plan-Do-Check-Act iterative process:

- *Plan* the security management system and create the policies that define it.
- *Do* implement the policies in your organization.
- *Check* to ensure the security management system's policies are protecting the resources they were meant to protect.
- *Act* to respond to incidents that breach the implemented policies.

Certifying your security management system helps ensure that you keep the controls and policies constantly up to date to meet certification requirements. Getting certified also demonstrates to your partners and customers that your security management systems will help keep your business running smoothly if network security events were to occur.

Though the ISO/IEC 27000 Family of Standards allows for businesses to optionally get certified, the Federal Information Security Management Act (FISMA) requires all government agencies to develop security management systems. The process of complying with FISMA is very similar to the process of implementing the ISO 27000 family of standards.

The first step of FISMA compliance is determining what constitutes the system you're trying to protect. Next, you need to perform risk assessment to determine what controls you'll need to put in place to protect your system's assets. The last step is actually implementing the planned controls. FISMA then requires mandatory yearly inspections to make sure an organization stays in compliance.

One of the advantages of the Sans 20 Critical Security Controls is the 20 individual touchstones that can be acted upon by the organization. It starts with some basic audit information. In step one you inventory all authorized and unauthorized devices. This may mean accessing each workstation and reviewing the system logs to identify if USB, Music, or phones have been plugged into the computer. The second step is to audit the software in the same way. Many times a user will download software and not know they have violated their organizations I.T. policies. These two basic checks need to be done annually for some organizations and more frequently for others. For more details access the SANS.ORG website.

2. TRAINING REQUIREMENTS

Many security management system training courses for personnel are available over the Internet. These courses

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00022-2

provide information for employees setting up security management systems and for those using the computer and network resources of the company that are referenced in the policies of the security management system.

Training should also include creating company security policies and creating user roles that are specific to the organization. Planning policies and roles, ahead of time, will help prevent confusion in the event of a problem, since everyone will know their responsibilities. Documenting these roles is also very important.

3. PRINCIPLES OF INFORMATION SECURITY

The act of securing information has been around for as long as the idea of storing information. Over time, three main objectives of information security have been defined:

- *Confidentiality*. Information is only available to the people or systems that need access to it. This is done by encrypting information that only certain people are able to decrypt or denying access to those who don't need it. This might seem simple at first, but confidentiality must be applied to all aspects of a system. This means preventing access to all backup locations and even log files if those files can contain sensitive information.
- *Integrity*. Information can only be added or updated by those who need to update that data. Unauthorized changes to data cause it to lose its integrity, and access to the information must be cut off to everyone until the information's integrity is restored. Allowing access to compromised data will cause those unauthorized changes to propagate to other areas of the system.
- *Availability*. The information needs to be available in a timely manner when requested. Access to no data is just as bad as access to compromised data. No process can be performed if the data on which the process is based is unavailable.

4. ROLES AND RESPONSIBILITIES OF PERSONNEL

All personnel who come into contact with information systems need to be aware of the risks from improper use of those systems. Network administrators need to know the effects of each change they make to their systems and how that affects the overall security of that system. They also need to be able to efficiently control access to those systems in cases of emergency, when quick action is needed.

Users of those systems need to understand what risks can be caused by their actions and how to comply with company policy. Several roles should be defined within your organization:

- *Chief information officer/director of information technology*. This person is responsible for creating and maintaining the security policies for your organization.
- *Network engineer*. This person is responsible for the physical connection of your network and the connection of your network to the Internet. He or she is also responsible for the routers, firewalls, and switches that connect your organization.
- *Network administrator*. This person handles all other network devices within the organization, such as servers, workstations, printers, copiers, tablets, video conference, smart phones, and wireless access devices. Server and workstation software is also the responsibility of the network administrator.
- *End users*. These people are allowed to operate the computer in accordance with company policies, to perform their daily tasks. They should not have administrator access to their PCs or, especially, servers.

There are also many other specific administrators some companies might require. These are Microsoft Exchange Administrators, Database Administrators, and Active Directory Administrators, to name a few. These administrators should have specific tasks to perform and a specific scope in which to perform them that is stated in the company policy.

5. SECURITY POLICIES

Each organization should develop a company policy detailing the preferred use of company data or company software. An example of a policy is: No person shall transfer any data to any device that was not purchased by the company. This policy can help prevent unauthorized access to company data. Some companies ban all removable media within the organization.

Security policies should govern how the computer is to be used on a day-to-day basis. Very often, computer users are required to have Internet access to do research pertaining to their jobs. This isn't hard to restrict in a specialized setting such as a law firm where only a handful of sites contain pertinent information. In other cases it can be nearly impossible to restrict all Web sites except the ones that contain information that applies to your organization or your research. In those cases it is imperative that you have company policies that dictate what Web sites users are able to visit and for what purposes. When unrestricted Internet access is allowed, it is a good practice to use software that will track the Web sites a user visits, to make sure they are not breaking company policy. For many companies they create a white list of

allowable sites, for others they use a black list to prevent certain sites from being accessed. Some of the more advanced firewalls give a list of categories that are allowed or blocked.

6. SECURITY CONTROLS

There are three types of security controls that need to be implemented for a successful security policy to be put into action. They are physical controls, technical controls, and administrative controls.

Physical controls consist of things such as magnetic swipe cards, RFID, or biometric security to prevent access to stored information or network resources. Physical controls also consist of environmental controls such as HVAC units, power generators, and fire suppression systems. One of the most common failures is people leaving their computers on and another person using their computer to gain access to information/data that they should not be allowed to access. Many companies utilize password screen savers or require a computer to be "locked" before they leave their workstation. Another common security measure is to encrypt the drives on a computer. One free whole disk encryption utility commonly deployed is True Crypt. (www.truecrypt.org). This prevents the data from being accessed from a stolen laptop or computer.

Technical controls can also be called software or system controls which are used to limit access to network resources and devices that are used in the organization. They can be individual usernames and passwords used to access individual devices or access control lists that are part of a network operating system. Many organizations are putting in password expiration dates of 30–60 days and even account deletion for accounts not accessed for more than 90 days. In addition, passwords that contain, numbers, upper and lowercase letters, special characters and have a length that exceeds 8 characters are required by some organizations in order to ensure stronger passwords.

Administrative controls consist of policies created by an organization that determine how they will work. These controls guide employees by describing how their jobs are to be done and what resources they are supposed to use to do them. This is probably the weakest section of each companies policies. The lack of written policies makes the implementation of security very difficult. More organizations should spend time setting up their policies and keep their employees up to date on what expectations they have for each employee.

7. NETWORK ACCESS

The first step in developing a security management system is documenting the network resources and which group of users may access those resources. Users should only have access to the resources that they need to complete their jobs efficiently. An example of when this will come in handy is when the president of the company wants access to every network resource and then his computer becomes infected with a virus that starts infecting all network files. Access Control Lists (ACLs) should be planned ahead of time and then implemented on the network to avoid complications with the network ACL hierarchy.

An ACL dictates which users have access to certain network resources. Network administrators usually have access to all files and folders on a server. Department administrators will have access to all files used by their departments. End users will have access to a subset of the department files that they need to perform their jobs. ACLs are developed by the head of IT for an organization and the network administrator and implemented by the network administrator.

Implementing ACLs prevents end users from being able to access sensitive company information and helps them perform their jobs better by not giving them access to information that can act as a distraction.

Access control can also apply to physical access as well as electronic access. Access to certain networking devices could cause an entire organization to stop functioning for a period of time, so access to those devices should be carefully controlled.

Through the use of Remote Authentication Dial In User Service (RADIUS) is an added layer of security to your network. Many of these systems employ a random number generator key fob's that displays a random number and changes it every 30–60 seconds. With this extra step of user authentication a person can combine a private key along with the random number to access the network. For example, an RSA SecureID token generates an 8 digit number, combine that with the users own 4 digit private password, an administrator can help to stop unauthorized access to their system.

8. RISK ASSESSMENT

Before security threats can be blocked, all risks must first be identified and assessed (see checklist: "An Agenda For Action When Identifying And Assessing Risks"). Risk assessment forms the foundation of a good security management system. Network administrators must document all aspects of their network setup. This documentation should provide information on the network firewall, servers, clients, and any other devices physically connected or wirelessly connected to the network.

9. INCIDENT RESPONSE

Knowing what to do in case of a security incident is crucial to being able to track down what happened and how

An Agenda for Action when Identifying and Assessing Risks

The most time should be spent documenting how the private computer network will be connected to the Internet for Web browsing and email. Some common security risks that should be identified and assessed are (check all tasks completed):

_____**1.** USB storage devices: Devices that can be used to copy proprietary company data off the internal network. Many organizations use software solutions to disable unused USB ports on a system; others physically block the connections.

_____**2.** Remote control software: Services such as GoToMyPc or Log Me In do not require any special router or firewall configuration to enable remote access.

_____**3.** Email: Filters should be put in place that prevent sensitive company information from simply being emailed outside the organization.

_____**4.** General Internet use: There is always a possibility of downloading a malicious virus from the Internet unless all but trusted and necessary Web sites are restricted to internal users. This can be accomplished by a content-filtering firewall or Web proxy server.

_____**5.** Laptops: Lost laptops pose a very large security risk, depending on the type on data stored on them. Policies need to be put in place to determine what types of information can be stored on these devices and what actions should be taken if a laptop is lost.

_____**6.** Peer-to-peer applications: P2P applications that are used to download illegal music and software cause a risk because the files that are downloaded are not coming from known sources. People who download an illegal version of an application could be downloading a worm that can affect the entire network.

_____**7.** Television/DVR/Blu-Ray Devices: With the expansion of technology, even televisions have internet access and storage.

_____**8.** VOIP telephones: The proliferation of Voice over IP telephones brings another device into our network environment. Some companies prefer to have their phones on a separate physical network, preventing slow response times and bad phone quality, while others have routers and switches that will prioritize the traffic of the phone calls in order to maintain good phone quality.

to make sure it never happens again. When a security incident is identified, it is imperative that steps are taken so that forensic evidence is not destroyed in the investigation process. Forensic evidence includes the content of all storage devices attached to the system at the time of the incident and even the contents stored in memory of a running computer.

Using an external hard drive enclosure to browse the content of the hard drive of a compromised system will destroy date and timestamps that a forensic technician can use to tie together various system events.

When a system breach or security issue has been detected, it is recommended to consult someone familiar with forensically sound investigation methods. If forensic methods are not used, it can lead to evidence not being admissible in court if the incident results in a court case.

There are specific steps to take with a computer system, depending on the type of incident that occurred. Unless a system is causing damage to itself by deleting files or folders that can be potential evidence, it is best to leave the system running for the forensic investigator. The forensic investigator will:

- Document what is on the screen by photographing it. He/She will also photograph the actual computer system and all cable connections.
- Capture the contents of the system's memory. This is done using a small utility installed from a removable drive that will create a forensic image of what is in the system's physical memory. This can be used to document Trojan activity. If memory is not imaged and the computer was used to commit a crime, the computer's user can claim that a malicious virus, which was only running in memory, was responsible.
- Turn off the computer. If the system is running a Windows workstation operating system such as Windows Vista Workstation or Windows Azure, the forensic technician will pull the plug on the system. If the system is running a server operating system such as Windows Server 2008, Windows 7 Server, Windows Server 2012, Windows 8 or a Linux- or Unix-based operating system such as Red Hat, Fedora, or Ubuntu, the investigator will properly shut down the system.
- Create a forensic image of the system's hard drive. This is done using imaging software and usually a hardware write-blocker to connect the system's hard drive to the imaging computer. A hardware write-blocker is used to prevent the imaging computer from writing anything at all to the hard drive. Windows, by default, will create a recycle bin on a new volume that it is able to mount, which would cause the evidence to

lose forensic value. Investigators are then able to search through the system without making any changes to the original media.

10. SUMMARY

Organizations interested in implementing a comprehensive security management system should start by documenting all business processes that are critical to an organization and then analyzing the risks associated with them, then implement the controls that can protect those processes from external and internal threats. Internet threats are not usually the cause of someone with malicious intent but someone who accidentally downloads a Trojan or accidentally moves or deletes a directory or critical files. The final step is performing recursive checking of the policies your organization has put in place to adjust for new technologies that need to be protected or new ways that external threats can damage your network. The easiest way to implement security management systems is to use the Plan-Do-Act-Check (PDAC) process to step though the necessary procedures. A locked door, a good password, and good supervision of employees is key to good security management.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? To give organizations a starting point to develop their own security management systems, the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC) have developed a family of standards known as the Information Security Management System 27000 Family of Standards.
2. True or False? Training should also include creating company security policies and creating user roles that are specific to the organization.
3. True or False? The act of securing information has not been around for as long as the idea of storing information.
4. True or False? All personnel who come into contact with information systems need to be aware of the risks from improper use of those systems.
5. True or False? Each organization should not develop a company policy detailing the preferred use of company data or company software.

Multiple Choice

1. _______ what is on the screen by photographing it?
   - **A.** Capture
   - **B.** Turn off
   - **C.** Document
   - **D.** Create
   - **E.** All of the above
2. _____the contents of the system's memory?
   - **A.** Turn off
   - **B.** Document
   - **C.** Create
   - **D.** Capture
   - **E.** All of the above
3. _____the computer?
   - **A.** Capture
   - **B.** Create
   - **C.** Document
   - **D.** Distribute
   - **E.** Turn off
4. _____a forensic image of the system's hard drive?
   - **A.** Create
   - **B.** Turn off
   - **C.** Capture
   - **D.** Document
   - **E.** All of the above
5. Devices that can be used to copy proprietary company data off the internal network are known as:
   - **A.** Remote control software
   - **B.** Email
   - **C.** USB storage
   - **D.** General Internet use
   - **E.** Risk analysis

1. INTRODUCTION

This chapter begins with a high-level view of security management and the development of security concepts, followed by an introduction of core concepts and terms relevant for PBM in particular, the layering of policies with different abstraction levels in a so-called policy hierarchy. Sections 3 and 4 explain high-level security objectives and principles, policies, and technologies relevant for the various policy abstraction levels and architecture layers in more detail, thereby putting particular focus on access control policies, related enforcement technologies, and selection criteria when touching lower abstraction levels. Section 5 summarizes the policy-related functionality of a small selection of existing products and technologies. As there does not yet exist a large-scale deployment of a policy-based computing system, all of the examples provide focus on selected aspects of PBM. Section 6 explains the approach of two research projects on the subject matter: Ponder, a project conducted in the early 1990s and considered a forerunner in this research domain, and PoSecCo, an ongoing EU research project that relates PBM to organizational structures and processes, seek to optimize and semiautomate the policy refinement process, and support policy-based configuration audits. The products and projects introduced in Sections 5 and 6 will be positioned with regard to the security life-cycle phases covered, policy types and abstraction levels supported, and architecture layers concerned. Note that we put special emphasis on access control (AC), thereby leaving other security-related topics and technologies aside (privacy or Digital Rights Management).

2. SECURITY AND POLICY-BASED MANAGEMENT

This section briefly summarizes today's practice with regard to security management, followed by a description of its deficiencies and an explanation of how PBM can help overcome them. Thereafter, we explain basic concepts of PBM and conclude with a short summary of autonomic computing, which aims at policy-based self-management of future information systems.

System Architecture and Security Management

IT systems are traditionally structured according to several architecture layers, each layer thereby offering a number of security capabilities that can support organizations in reaching desired security objectives. Architectures that exemplify the layered structure of IT systems are the three-tier architecture of Web applications, or, more recently, the cloud computing reference architecture [1]. Typical architecture layers comprise, for instance, user frontends, software services, and applications that implement the business logic, platform services that provide a runtime environment, or infrastructure services that offer connectivity or computing resources.

Ideally, capabilities offered on different layers are combined in a complementary manner as to implement *Defense in Depth*, a security principle recommending the setup of multiple, complementary lines of defense against malicious attacks or other threats to security. Since many of the

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00023-4

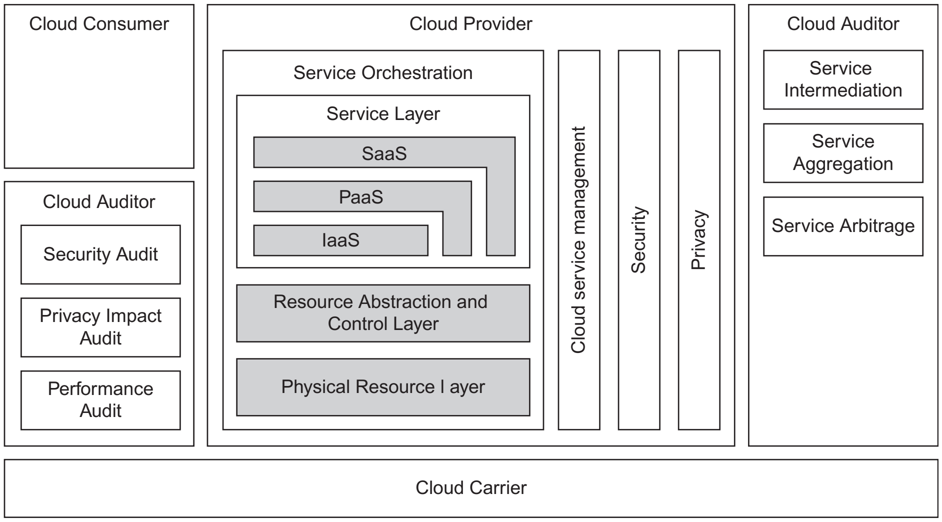

FIGURE 23.1 NIST cloud computing reference architecture [1].

security mechanisms[1] employed on different layers do not work in isolation but impact each other, security is typically seen to be orthogonal to the various technology layers in order to have a holistic view of security (cf. Figure 23.1). This view is also supported by the IT Infrastructure Library[2] (ITIL), a widely adapted methodology for the management of IT services, which aims at overcoming IT silos— specialized people, expertise, and tools that focus on the management of system slices (databases or networks).

High-level security objectives, common controls, as well as processes regarding the design, implementation, and operation of an information security management system and a security concept are described in various standards and guidelines (the ISO 27000 series of standards as well as national adaptations[3]). These processes structure the design of secure systems in several phases that generally follow the idea of the Plan-Do-Check-Act (PDCA) cycle introduced by [3].

The *Plan* phase starts with the specification of security objectives and the definition of protection requirements by C-level executives, data protection officers, or business stakeholders. Larger organizations and those known to have special requirements can do this on the basis of a comprehensive risk analysis, while others follow a best-practice approach. Other sources of high-level objectives comprise general laws and regulations (SOX or privacy laws) or industry-specific standards such as those from the U.S. Food and Drug Administration (FDA), or the Data Security Standard (DSS) authored by the Payment Card Industry (PCI), which is relevant for every organization that stores or processes cardholder information [4].

Once those high-level objectives are defined, suitable security controls need to be identified and assessed by means of a cost-benefit analysis; as a result, some of the controls will be selected for implementation. This activity is complicated by the fact that the security capabilities of controls residing on different architecture layers can overlap and even conflict. Application servers, for instance, also support IP address filtering.[4] Firewalls, as another example, emerged to analyze application-level communication protocols.

The *Do* phase sees the implementation of security controls, which includes, among other activities, the transformation of high-level policies to a representation that can be interpreted by the security mechanisms selected. Here, system and security administrators knowledgeable in the various technologies enter the scene. The *Check* phase concerns the performance review and monitoring of security mechanisms as to understanding whether they are still suitable to meet the initial objectives (design effectiveness) and whether they work as designed (operation effectiveness). Finally, the *Act* phase covers continuous improvements of the security mechanisms in reaction to (small) requirement and system changes.

The Promise of Policy-based Management

Security management as performed today involves a variety of stakeholders with different job functions, expertise,

1. Note that we use the terms *security mechanism* and *security control* interchangeably in order to denote a technical security capability provided by software or hardware components. In other contexts, the term *security control* typically has a broader meaning, and denotes technical and nontechnical measures to reach a given security objective.
2. http://www.itil-officialsite.com
3. The Federal Office for Information Security (BSI) in Germany, for example, maintains the standard BSI 100-1 to describe general requirements for an Information Security Management System (ISMS) in greater detail and following a more didactic approach [2].
4. The Apache HTTP Server, for example, supports AC rules with conditions over source IP addresses or domain names.

and objectives, and the use of different tools and terminology. Human-centric processes, however, are the main contributor to the significant increase of costs related to system management. On average, 70 percent of IT budgets are spent to maintain and manage current IT infrastructures [5]. And despite significant spending, many organizations "cannot prove enforcement [of security policies] or it is prohibitively expensive to do so" [6]. At the same time, human intervention is prone to errors, in particular when it comes to repetitive tasks involving low-level technology aspects. A series of studies show that inaccurate configuration settings are among the most common reasons for insecure and incompliant systems, many times leading to actual data breaches [7,8]. A UK security report, for instance, found that, "whilst many of the organizations investigated actually had firewalls installed, poor configuration of these devices rendered most of them useless" [9]. Moreover, "in over 96% of cases, ... PCI DSS was not adequately adhered to." Inaccurate configurations are typically introduced during the implementation and operations phase of a security concept, for instance, when configurations are altered to reflect system or business process changes.

In light of the above, the promise of PBM with regard to system management is twofold. On the one hand, it aims at reducing management costs by the automation of activities that today require human intervention. On the other hand, it aims at improving service quality (in part through the avoidance of human failure). Both goals shall be achieved by sparing humans from low-level and repetitive tasks that relate to technical implementation details of IT systems.

One property of policy-based systems that contributes to these goals is the fact that security decision rules of system elements are not represented by hard-coded algorithms, which would result in modifications or replacements of system elements whenever security rules change. Policy-based systems instead rely on declarative statements made available to and interpreted by the respective system element. This separation of policy specification and enforcement is cost-beneficial and increases the flexibility to adapt a system to changing security requirements.

PBM aligns very well with the security life cycle, since both of them follow a top-down approach that starts with the specification of high-level objectives and ends with the enforcement of low-level policies by security mechanisms. In PBM, high-level security objectives that control overall system behavior are still given by humans, but subsequent steps related to the selection, implementation, and operation of appropriate mechanisms become more and more automated.

In order to reach its goals, PBM must address the following problems: the identification, assessment, and selection of appropriate security mechanisms, the refinement of higher-level policies to lower-level representations until a point where selected enforcement mechanisms can interpret them, the analysis and resolution of policy conflicts occurring on several abstraction levels, within and across policy enforcement mechanisms, and, finally, the organization of policies and their distribution to enforcement devices.

Policy Basics

Generally speaking, a *policy* is a "definite goal, course or method of action to guide and determine present and future decisions" [10]. The term policy is broadly used in the domain of computer science and information security, and denotes many different things (firewall policies, access control policies, acceptable use policies, or security policies). Sometimes, the term refers to a single policy rule, and in other contexts to a collection of such rules.

For our purposes, a policy constrains the behavior of computing systems. More formally, following [11], a policy is defined over a target system, which is associated with a number of attributes that have a certain type, and all of which together determine the system state. The behavior of a system is then defined as a continuous ordered set of states, where the order is imposed by time. Considering the set of all possible behaviors, a policy represents a set of constraints on the possible behaviors (it defines a subset of acceptable behaviors). Based on this generic definition, in [11] policies are classified into different types, in particular *configuration constraint policies* that constrain the values of configurable system attributes, *metric constraint policies* that constrain observable but not directly influenceable attributes, *action policies* that, upon the observation of a given state, trigger operations in order to reach a desired target state, and *alert policies* that notify users as soon as the system state satisfies certain conditions.

A password policy, for instance, that demands a certain password length and complexity can be considered as a configuration constraint policy over attributes belonging to an authentication mechanism. An access control policy, for instance, can be considered as an action policy, where the condition is defined over attributes of the subject, resource, or other entities, and the action is either deny or allow.

While the generality of the above definition covers a broad range of policies, many more specific definitions were created for single policy application domains. In that context, *policy information models* are often used to visualize the constituting policy elements and their structural relationships. Condition-Action (CA) and Event-Condition-Action (ECA) hereby represent very basic policy models, where a single action or set of actions are to

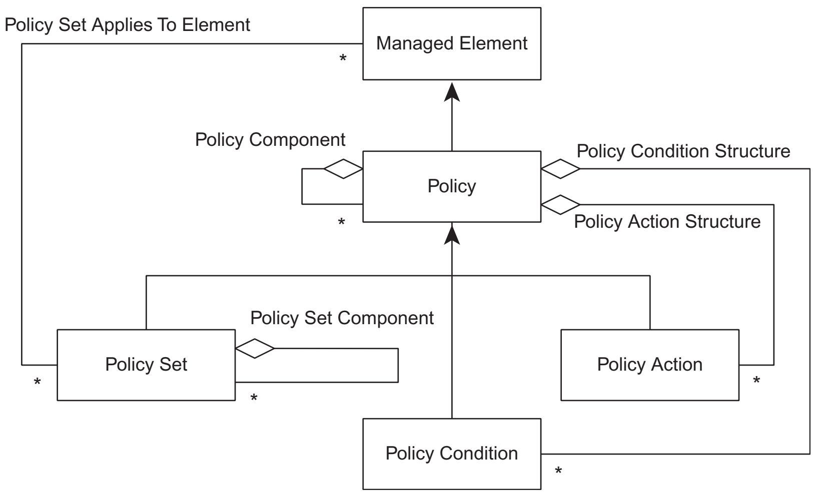

FIGURE 23.2 CIM policy model [12].

be executed upon certain conditions.[5] The CIM Policy Model, for instance, uses UML to model the structure of CA policies that can be associated with CIM managed elements (see Figure 23.2).[6]

Security-related information models such as for AC typically specify conditions under which a subject can be granted to perform an operation defined over a target (or resource). On first sight, typical AC policy models seem to differ from the CA/ECA models mentioned before. However, this is only because event and action are not made explicit but exist implicitly in the form of the access request issued by the subject, and the deny or allow action that determines whether access can be granted.

Information models are useful for illustrating the conceptual structure of policies, but *policy languages* are required to represent concrete policies. A plethora of such languages exist, ranging from natural language for the expression of high-level policies on the one hand to precise mathematical models to support computer-based reasoning on the other hand. In many cases, the syntax and vocabulary of a policy language are tailored to a specific application domain, and some languages were designed without explicitly denoting the underlying information model. XACML, for instance, is a widely used XML-based language for expressing access control policies. CIM-SPL (Simple Policy Language), for instance, can be used to represent CIM policies according to the CIM Policy Model.

Policy Hierarchy and Refinement

The PBM approach naturally leads to a so-called policy continuum [13], a hierarchy of policies that are subject to different abstraction levels. Such policies undergo an iterative refinement process that transforms high-level and abstract policies into lower-level representations that can be eventually interpreted by enforcement mechanisms situated in a given IT system.

The highest policy abstraction level is typically referred to as business view [14], goal policies [15,16],[7] corporate policies [17], or high-level user-specified policies [11]. Such policies use business terms and relate to, for instance, corporate goals, business-critical risks, or regulatory and legal requirements. They abstract from the IT system in question and often specify goals without detailing how to attain them. They are typically authored by management and business users that indeed neither need nor want to depend on technology when specifying business goals. Being independent from the IT system, business policies typically remain more stable than lower-level representations that are more exposed to system changes. Since business policies are often written in an informal and possibly ambiguous way (with the support of spreadsheets and policy documents, they are seldom subject to automated reasoning that supports the detection of policy conflicts).

The PCI DSS requirement, which demands the use of "strong cryptography and security protocols to safeguard cardholder data during transmission over public networks," is a typical example for a high-level business policy [4]. It merely states an objective without prescribing a specific enforcement technology, and it remains agnostic of a given IT system. "Response time must not exceed 2 sec" is another example for a high-level goal policy [16], since it does not specify suitable actions to improve the response time once the threshold is reached.

The number of intermediate abstraction levels following business policies varies between the various

5. The ECA model also specifies the event that triggers the evaluation.
6. The Common Information Model (CIM) is a DMTF standard that uses an object-oriented approach to model computing systems and today is widely used in IT management systems.

7. Though in [16] utility function policies are considered as the highest policy level, we consider them here as meta-policies that define the relative importance of goal policies.

classification schemes. In [16], for instance, action policies are presented that specify how a goal policy can be reached, and in [11] a distinction is made between abstract, technology-independent and concrete, technology-specific policies as intermediate levels. Common to the transformation of higher to lower abstraction levels is that policies are step-by-step enriched with additional details, thereby keeping the policy structure intact. Policy goals become substituted by actions and mechanisms that support reaching the goal. In order to enforce the PCI DSS requirement, for instance, one has to specify the security technology to be used (SSL/TLS or IPsec). As another example, the action policy “Increase CPU share by 5% if response time exceeds 2 sec” refines the above goal policy, thereby using the form Condition-Action. Moreover, policy components such as subjects, targets, conditions, or actions become refined and enriched until they correspond to identifiable elements in a given IT system. Logical roles, for instance, are substituted by technical roles used in the respective system components, or logical names for computers or groups of computers become substituted by IP addresses or address ranges. The kind of lower-level information to be enriched depends on the enforcement mechanism chosen (IP addresses for network-level firewalls vs. protocols or URLs for application-level firewalls), while the actual information is determined by the system in question.

The lowest policy abstraction level is typically referred to as executable or deployment policies [11], or policy mechanism information [15]. These policies can be deployed into and interpreted by a given system component, which then acts as a policy enforcement point. The format or language to express executable policies depends on technologies and vendors. Typical examples for executable policies are, for instance, configuration parameters that establish the use of Transport Layer Security (TLS) for Internet-facing Web applications that process cardholder data, or a configuration rule that increases or decreases the priority of operating system processes depending on response time changes. It is noteworthy that system management tools available today typically focus on a subset of policy representations instead of taking a holistic view on the entire policy hierarchy. Microsoft Group Policy, for instance, concentrates only on the executable policy layer but does not support policy analysis or translation of upper-layer policy representations. SAP Access Control, as another example, supports concrete policies for role-based access control systems and their translation to vendor-specific representations on the executable policy layer.

Policy Organization and Conflicts

Larger systems make it impractical to specify policies for individual system elements. Accordingly, PBM must support the grouping of both policies and system elements to facilitate the scoping of policies (the specification of system elements to which a given set of policies shall apply). Today, system management is typically structured by administrative domains that govern a subset of the entire system, which is organized in a hierarchical fashion. This hierarchy is then used to group system elements and policies.

Microsoft Group Policy, for instance, supports the linking of policies to a hierarchy of domains, sites, and organizational units. In [15] the term *managed domain* was introduced to denote a collection of managed objects that are grouped for management purposes. In [11] the use of roles is presented as a means to group policies. Policies for (Web servers can be created, distributed, and evaluated as a group).

Once a set of policies is somehow structured and assigned to managed elements, the system has to determine which policy or policies shall be evaluated in the course of a given event. This selection is supported by different strategies, sometimes considering the entire set of policies, sometimes terminating the search as soon as an applicable policy is found. Policies assigned to tree structures allow, for instance, preference of more specific over more general policies or vice versa. A strategy implemented by most firewalls is to order policy rules, evaluate the first one with matching conditions, and ignore the rest. Other means are to prioritize policies and evaluate the one with the highest priority in case several policies have matching conditions, or to specify meta-policies.

Moreover, a group of policies can be subject to anomalies and conflicts. A (modal) policy conflict between, for instance, firewall policy rules arises if two rules have overlapping conditions (on the source IP address), but conflicting actions (allow and deny). As another example, a modal conflict between obligation and access control policies exist if a subject is obliged to perform a given action but does not have the required authorization [18]. Such conflicts are relatively easy to spot in case they concern just one enforcement point (a firewall), but are more complex if several enforcement points are concerned. Accordingly, continuing the firewall example, a classification is presented in [19] of intra- and inter-firewall policy conflicts (conflicts that arise from the interpretation of policy rules by a single firewall and those that result from a sequence of policy evaluations performed by several firewalls). Furthermore, conflicts can also occur between policies targeting different architecture layers, which are again more difficult to identify and require a holistic view on policies. More details on policy conflicts can be found in Chapter 45, Detection of Conflicts in Security Policies.

Policy Distribution

Once refined to low-level representations (executable policies according to the terminology used by) [11],

policies need to be distributed to those system elements that need to evaluate and enforce them at system runtime. To overcome problems inherent to manual deployment, a variety of tools support administrators in the automated deployment of policies in large-scale distributed systems.

Today, such tools include, on the one hand, tailor-made configuration scripts that copy configuration files by, for instance, means of Secure Shell (SSH) connections. This category of tools also comprises, on the other hand, configuration management systems such as SAP Solution Manager or HP OpenView, which maintain central configuration repositories, support versioning, and implement ITIL-defined workflows in order to prevent unauthorized and erroneous configuration changes. Other examples comprise Local Configuration (LCFG), a large scale UNIX configuration system that facilitates configuration management in UNIX environments, and Microsoft Group Policy, which supports Windows environments. Configuration management systems increase the correctness and consistency of configuration information, speed up deployment processes, and support a variety of other security-related activities such as IT audits. However, they do not yet free humans from the burden of dealing with low-level details of system management, since the initial specification of low-level configuration parameters is still left to administrators. In other words, they cover neither high-level policy representations nor the translation from abstract policies to concrete configuration parameters.

Generic Policy Architecture

Policy-based systems require a set of common functionalities related to the creation, storage, distribution, and enforcement of policies. The standardization bodies Internet Engineering Task Force (IETF) and Distributed Management Task Force, Inc. (DMTF) started defining a generic architecture for policy-based systems [20], which was subsequently refined and now represents a common basis for policy-related work, thereby abstracting from specific technologies, vendors, or types of policies.

In this generic architecture, the policy administration point (PAP) provides a user interface to allow end users to create, translate, validate, and manage policies that will be stored in a policy repository. At system runtime, a policy decision point (PDP) identifies and evaluates applicable policies provided by the repository in order to decide whether appropriate actions need to be taken. In the course of policy evaluation, a policy information point (PIP) supplies complementary information required for taking a policy decision. Last, the so-called policy enforcement point (PEP) is responsible for ensuring that the outcome of policy decisions is enforced in the system.

The runtime interaction of these components can be illustrated as the example of an access request to a protected resource (cf. Figure 23.3). Here, the PEP mediates any access request of a user to a protected resource. The PEP sends a corresponding request to the PDP, thereby providing identifiers of the authenticated user and the protected resource. The PDP searches for applicable policies and seeks complementary information from the PIP, for instance, user-role assignments stored in an LDAP directory. The Policy Decision Point (PDP) terminates the policy evaluation by deciding whether access to this resource shall be denied or granted to the user in question, which in turn will be enforced by the PEP. The preceding could be implemented with the help of, for instance, XACML, which not only specifies a language for the definition of access control policies, but also defines a protocol for the interaction of PEP and PDP.

Note that most of today's security mechanisms, including some of those presented later in this chapter, implement several of these policy-related functions in an integrated manner, rather than supporting a clean, protocol-based separation as outlined by the generic architecture. Firewalls, for instance, typically integrate the functionalities of PEP, PDP,

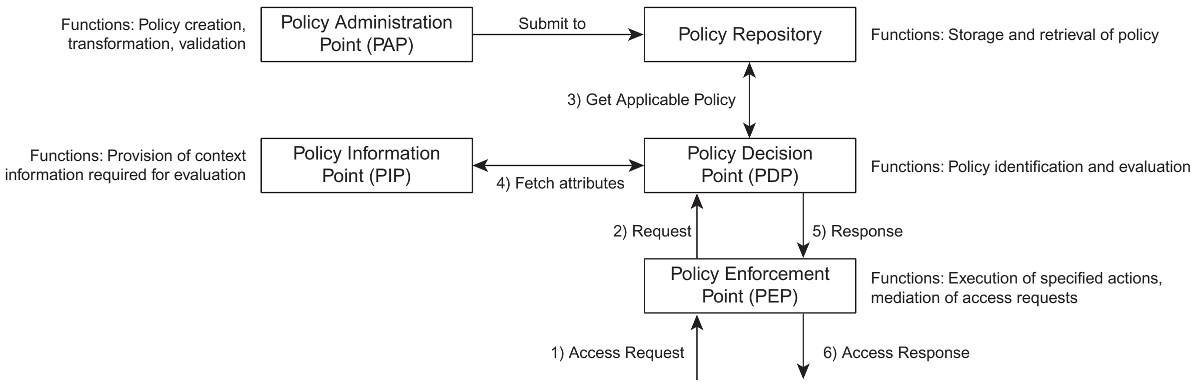

FIGURE 23.3 Generic architecture of policy-based systems.

and repository, which is motivated by significant performance advantages compared to a communication of possibly distributed components.

Autonomic Computing

The term *autonomic computing* has been coined by IBM to denote computing systems that manage themselves [21]. Inspired by biological and social systems, autonomic (computing) systems are composed of autonomic elements (aka agents) that autonomously enforce high-level policies they were provided with by humans or other system elements, and thereby discover, interact, and negotiate with other autonomic elements. Two out of the four self-management properties stipulated by IBM are *self-protection* and *self-healing*. Self-protection refers to the capability of autonomic systems to detect and correlate distributed events that result from attacks, cascading failures, or problematic changes inadvertently introduced by users, and to react appropriately in order to defend the system against security compromise. Self-healing concerns the detection, diagnosis, and correction of localized problems that result from software bugs or hardware failures. The correction of a software bug could result, for instance, in the search, application, and test of software patches. The contribution of IBM's autonomic computing manifesto [22] does not primarily concern technology; the foundation was already laid, but in giving perspective to the future and long-term development of IT, as a means to tie several research domains to a bigger context, and to address nontechnical questions that emerge when IT components behave in an autonomous fashion.

As illustrated by Figure 23.4, an autonomic element comprises an autonomic manager, which seeks enforcing the policy by observing and manipulating one or several managed elements under its control. Managed elements essentially correspond to software as it exists today, and all of the security mechanisms presented in Section 5 can be managed elements. The autonomic manager monitors managed elements through the use of sensors, analyzes such information, and, where necessary, plans appropriate actions that are executed through effectors. In the course of policy distribution, and in contrast to existing distribution technologies, the autonomic manager receives a high-level policy that must be refined to lower-level representations understood by its managed elements. Policy translation as well as the analysis and planning phases of the MAPE-K (Monitor, Analyze, Plan, Execute, Knowledge) control loop are guided by a knowledge base populated by the agent developer. In case managed elements do not provide a required security capability by themselves, a software agent may also act as a policy enforcement point. Ponder, for instance, relies on agents to enforce authorization policies specified over the target managed element.

Accreditation

The following checklist addresses accreditation criteria for security and policy-based management (see checklist: An Agenda for Action When Addressing Accreditation Criteria for Security and Policy-Based Management) systems. The numbering of this checklist generally follows the numbering of other checklists found in the rest of the book, as well as, other tasks that must be completed:

- All items on this checklist shall be addressed.
- Place an "X" beside each item that represents a nonconformity (formerly called deficiency).
- Place a "C" beside each item on which you are making a comment.
- Place an "OK" beside each item that you observed or verified at the laboratory.

3. CLASSIFICATION AND LANGUAGES

The availability of tools for policy-based security management will support the realization of all the classical security objectives, such as confidentiality, integrity, availability. Indeed, the design of a secure system, in most cases, separately considers each of the objectives, whereas a holistic view is needed in order to capture the interdependencies that exist among separate security services. For instance, the specification of authorizations requires the availability of adequate authentication

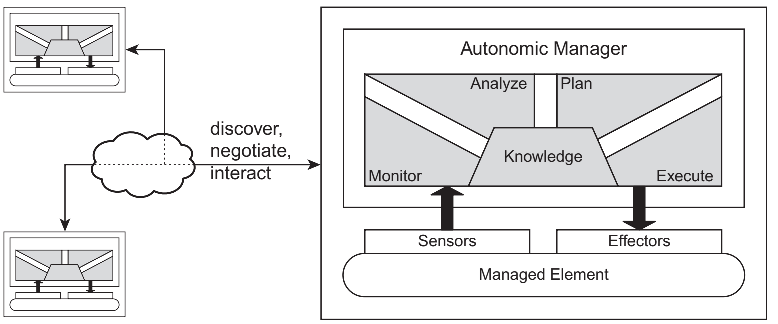

FIGURE 23.4 MAPE-K reference model for autonomic elements

An Agenda for Action When Addressing Accreditation Criteria for Security and Policy-Based Management

All organizations must adhere to the following accreditation process (check all tasks completed):

_____**1.** The management system documentation was most recently reviewed on _________________. Changes and additions required by the reviewers were made by the laboratory.

_____**2.** The management system documentation was found adequate for *continuation of the assessment process.*

_____**3.** Changes and additions to the management system documentation, which were required by the reviewers, were made by the laboratory.

_____**4.** The initial on-site was conducted on _________________.

_____**5.** Resolutions of findings from the initial on-site visit will be reviewed during the assessment visit.

_____**6.** The results of the initial evaluations have been read and will be reviewed during the assessment visit.

_____**7.** The laboratory shall establish and maintain policies and procedures for maintaining laboratory impartiality and integrity in the conduct of information technology security evaluations.

_____**8.** When conducting evaluations under the NIAP Common Criteria Scheme, the laboratory policies and procedures shall ensure that:

_____**a.** Laboratory staff members cannot both develop and evaluate the same Protection Profile, Security Target, or IT product.

_____**b.** Laboratory staff members cannot provide consulting services for and then participate in the evaluation of the same Protection Profile, Security Target, or IT product.

_____**9.** The laboratory shall have physical and electronic controls augmented with an explicit policy and set of procedures for maintaining separation, both physical and electronic, between the laboratory evaluators and laboratory consultants, product developers, system integrators, and others who may have an interest in and/or may unduly influence the evaluation outcome.

_____**10.** The management system shall include policies and procedures to ensure the protection of proprietary information.

_____**11.** The protection of proprietary information protection shall specify how proprietary information will be protected from persons outside the laboratory, from visitors to the laboratory, from laboratory personnel without a need to know, and from other unauthorized persons.

_____**12.** The management system requirements are designed to promote laboratory practices that ensure the technical accuracy and integrity of the security evaluation and adherence to quality assurance practices appropriate to common criteria testing.

_____**13.** The laboratory shall maintain a management system that fully documents the laboratory's policies, practices, and the specific steps taken to ensure the quality of the IT security evaluations.

_____**14.** The reference documents, standards, and publications, shall be available for use by laboratory staff developing and maintaining the management system and conducting evaluations.

_____**15.** Each applicant and accredited laboratory shall have written and implemented procedures.

_____**16.** Records shall be kept of all management system activities.

_____**17.** The procedures for review of contracts shall include procedures to ensure that the laboratory has adequate staff and resources to meet its evaluation schedule and complete evaluations in a timely manner.

_____**18.** The laboratory shall maintain a functional recordkeeping system that is used to track each security evaluation.

_____**19.** Records shall be easily accessible and contain complete information for each evaluation.

_____**20.** Required records of evaluation activities shall be traceable to common criteria evaluator actions and common evaluation methodology work units.

_____**21.** Computer-based records shall contain entries indicating the date created and the individual(s) who performed the work, along with any other information required by the management system.

_____**22.** Entries in laboratory notebooks shall be dated and signed or initialed.

_____**23.** All records shall be maintained in accordance with laboratory policies and procedures and in a manner that ensures record integrity.

_____**24.** There shall be appropriate back-ups and archives.

_____**25.** There must be enough evaluation evidence in the records so an independent body can determine what evaluation work was actually performed for each work unit and can concur with the verdict.

_____**26.** Records should include evaluator notebooks, records relating to the product, work-unit level records, and client-site records.

_____**27.** Laboratory records shall be maintained, released, or destroyed in accordance with the laboratory's proprietary information policy and contractual agreements with customers.

_____**28.** Records covering the following are required:

_____**a.** All quality system activities.

_____**b.** Staff training dates and competency reviews.

_____**c.** All audits and management reviews.

_____**d.** Creation of and changes to evaluation procedures and methodology.
_____**e.** Acceptance/rejection of products submitted for evaluation.
_____**f.** Complete tracking of multiple versions of evaluation evidence and evaluation technical reports.
_____**g.** Complete tracking of evaluation activities to the work-unit level including initial analysis, verdicts, and any subsequent changes to those verdicts (based on modifications of evidence or additional analysis).
_____**h.** Source code, binary executables, data and configuration information sufficient to reproduce any testing performed during the evaluation must be retained; this includes source code and binary executables for any test tools (when available) along with test data and configuration information/files.
_____**i.** Calibration records for any equipment where reported results include an estimate of error.
_____**j.** The calibration records should include: the range of calibration, the resolution of the instrument and its allowable error, calibration date and schedule, date and result of last calibration, identity of the laboratory individual or external service responsible for calibration; and source of reference standard and traceability.
_____**k.** The configuration of all test equipment used during an evaluation along with analysis of that equipment to confirm the suitability of test equipment to perform the desired testing.

_____**29.** The internal audit shall cover the laboratory management system and the application of the management system to all laboratory activities.
_____**30.** The audit shall cover compliance with contractual and laboratory management system requirements.
_____**31.** Audits shall cover all aspects of the evaluation activities, including the evaluation work performed.
_____**32.** In the case where only one member of the laboratory staff is competent to conduct a specific aspect of a test method, and performing an audit of work in this area would result in that person auditing his or her own work, then audits may be conducted by another staff member.
_____**33.** The audit shall cover the evaluation methodology for that test method and shall include a review of documented procedures and instructions, adherence to procedures and instructions, and review of previous audit reports.
_____**34.** External experts may also be used in these situations.
_____**35.** The most recent internal audit report shall be available for review during on-site assessments.
_____**36.** The laboratory shall perform at least one complete internal audit prior to the first full on-site assessment.
_____**37.** A partial internal audit should be performed prior to the initial on-site assessment.
_____**38.** The records will be reviewed before or during the on-site assessment visit.
_____**39.** The most recent management review report shall be available for review during on-site assessments.
_____**40.** The laboratory shall perform at least one management review prior to the first full on-site assessment.
_____**41.** A management review should be performed prior to the initial on-site assessment.
_____**42.** The records should be reviewed before or during the on-site assessment visit.
_____**43.** The quality manual shall contain, or refer to, documentation that describes and details the laboratory's implementation of procedures covering all of the technical requirements.
_____**44.** The laboratory shall maintain a competent administrative and technical staff appropriate for common criteria-based IT security evaluations.
_____**45.** The laboratory shall maintain position descriptions, training records, and resumes for responsible supervisory personnel and laboratory staff members who have an effect on the outcome of security evaluations.
_____**46.** The laboratory shall maintain a list of personnel designated to fulfill requirements, including: laboratory director, Authorized Representative, Approved Signatories, evaluation team leaders, and senior evaluators.
_____**47.** The laboratory shall also identify a staff member as quality manager who has overall responsibility for the management system, the quality system, and maintenance of the management system documents.
_____**48.** An individual may be assigned or appointed to serve in more than one position; however, to the extent possible, the laboratory director and the quality manager positions should be independently staffed.
_____**49.** When key laboratory staff are added, the notification of changes shall include a current resume for each new staff member.
_____**50.** Laboratories shall document the required qualifications for each staff position.
_____**51.** The staff information may be kept in the official personnel folders or in separate, official folders that contain only the information that the assessors need to review.
_____**52.** Laboratory staff members who conduct IT security evaluation activities shall have a Bachelor of Science in Computer Science, Computer Engineering, or related technical discipline or equivalent experience.

_____**53.** Laboratory staff collectively shall have knowledge or experience in the following areas: operating systems, data structures, design/analysis of algorithms, database systems, programming languages, computer systems architectures, and networking.

_____**54.** In addition, the laboratory staff shall have knowledge or experience for any specific technologies upon which an evaluation is conducted.

_____**55.** The laboratory shall have documented a detailed description of its training program for new and current staff members.

_____**56.** Each new staff member shall be trained for assigned duties.

_____**57.** The training program shall be updated and current staff members shall be retrained when the common criteria, common evaluation methodology, or scope of accreditation changes, or when the individuals are assigned new responsibilities.

_____**58.** Each staff member may receive training for assigned duties either through on-the-job training, formal classroom study, attendance at conferences, or another appropriate mechanism.

_____**59.** Training materials that are maintained within the laboratory shall be kept up to date.

_____**60.** Staff members shall be trained in the following areas:

- _____**a.** general knowledge of the test methods including generation of evaluation reports
- _____**b.** computer science concepts
- _____**c.** computer security concepts
- _____**d.** working knowledge of the common criteria
- _____**e.** working knowledge of the common cethodology

_____**61.** The laboratory shall review annually the competence of each staff member for each test method the staff member is authorized to conduct.

_____**62.** The staff member's immediate supervisor, or a designee appointed by the laboratory director, shall conduct annually an assessment and an observation of performance for each staff member.

_____**63.** A record of the annual review of each staff member shall be dated and signed by the supervisor and the employee.

_____**64.** A description of competency review programs shall be maintained in the management system.

_____**65.** Individuals hired to perform common criteria testing activities are sometimes referred to as "subcontractors."

_____**66.** To that end, all individuals performing evaluation activities must satisfy all requirements, irrespective of the means by which individuals are compensated.

_____**67.** The records for each staff member having an effect on the outcome of evaluations shall include: position description, resume/CV/bio (matching person to job), duties assigned, annual competence review, and training records and training plans.

_____**68.** In order to maintain confidentiality and impartiality, the laboratory shall maintain proper separation between personnel conducting evaluations and other personnel inside the laboratory or outside the laboratory, but inside the parent organization.

_____**69.** The laboratory shall have adequate facilities to conduct IT security evaluations.

_____**70.** This (checklist number 69) includes laboratory facilities for security evaluation, staff training, recordkeeping, document storage, and software storage.

_____**71.** A protection system shall be in place to safeguard customer proprietary hardware, software, test data, electronic and paper records, and other materials.

_____**72.** The protection system shall protect the proprietary materials and information from personnel outside the laboratory, visitors to the laboratory, laboratory personnel without a need to know, and other unauthorized persons.

_____**73.** Laboratories shall have systems (firewall, intrusion detection) in place to protect internal systems from untrusted external entities.

_____**74.** If evaluation activities are conducted at more than one location, all locations shall meet the requirements and mechanisms shall be in place to ensure secure communication between all locations.

_____**75.** The laboratory shall have regularly updated protection for all systems against viruses and other malware.

_____**76.** The laboratory shall have an effective backup system to ensure that data and records can be restored in the event of their loss.

_____**77.** If the laboratory is conducting multiple simultaneous evaluations, it shall maintain a system of separation between the products of different customers and evaluations.

_____**78.** This (checklist number 77) includes the product under evaluation, the test platform, peripherals, documentation, electronic media, manuals, and records.

_____**79.** PKI enabled electronic mail capability is required for communications.

_____**80.** Internet access also is required for obtaining revisions to the common criteria, common evaluation methodology, guidance, and interpretations.

_____**81.** Evaluation activities will be conducted outside of the laboratory, and the management system shall include appropriate procedures for conducting security evaluation activities at customer sites or other offsite locations.

_____**82.** The customer site procedures should explain how to secure the site, where to store records

and documentation, and how to control access to the test facility.

_____**83.** If the laboratory is conducting its evaluation at the customer site or other location outside the laboratory facility, the environment shall conform, as appropriate, to the requirements for the laboratory environment.

_____**84.** If a customer's system on which an evaluation is conducted is potentially open to access by unauthorized entities during evaluation, the evaluation laboratory shall control the evaluation environment.

_____**85.** This (checklist number 84) is to ensure that the systems are in a defined state compliant with the requirements for the evaluation before starting to perform evaluation work and that the systems ensure that unauthorized entities do not gain access to the system during evaluation.

_____**86.** The test methods of ISO/IEC 17025 are analogous to evaluation methodology using the common criteria (CC), the common evaluation methodology (CEM), and additional laboratory-developed methodology.

_____**87.** The version of the CC and CEM to be used in each evaluation shall be established in consultation with NIAP and the sponsor.

_____**88.** For the purposes of achieving product validation through the common criteria scheme, laboratories may be required to comply with both international interpretations and NIAP-specified guidance.

_____**89.** The common criteria, common evaluation methodology, guidance and interpretations, and the laboratory's procedures for conducting security evaluations shall be maintained up to date and be readily available to the staff.

_____**90.** The laboratory shall have documented procedures for conducting security evaluations using the common criteria and common evaluation methodology, and for complying with guidance or interpretations

_____**91.** The laboratory shall ensure that documented procedures are followed.

_____**92.** Security evaluations may be conducted at the customer site, the laboratory, or another location that is mutually agreed to.

_____**93.** When evaluation activities are conducted outside the laboratory, the laboratory shall have additional procedures to ensure the integrity of all tests and recorded results.

_____**94.** The additional procedures shall also ensure that the same requirements that apply to the laboratory and its facility are maintained at the nonlaboratory site.

_____**95.** When exceptions to the evaluation methodology are deemed necessary for technical reasons; and to ensure that the new methodology continues to meet all requirements and policies, the customer shall be informed, and details of these exceptions shall be described in the evaluation report.

_____**96.** The laboratory shall maintain on-site systems adequate to support IT security evaluations in keeping with the tests for which it is seeking accreditation.

_____**97.** The laboratory shall have an electronic report generation capability.

_____**98.** The laboratory shall document and maintain records on all test equipment or test suites used during common criteria testing.

_____**99.** The laboratory is responsible for configuration and operation of all equipment within its control.

_____**100.** Computer systems and other platforms used during the conduct of testing shall be under configuration control.

_____**101.** The laboratory shall have procedures to ensure that any equipment (hardware and software) used for testing is in a known state prior to use for testing.

_____**102.** Measurement traceability is required when applicable.

_____**103.** The equipment used for conducting security evaluations shall be maintained in accordance with the manufacturer's recommendations, or in accordance with internally documented laboratory procedures, as applicable.

_____**104.** Test equipment refers to software and hardware products or other assessment mechanisms used by the laboratory to support the evaluation of the security of an IT product.

_____**105.** Laboratories shall calibrate their test equipment.

_____**106.** In common criteria testing, calibration means verification of correctness and suitability.

_____**107.** Any test tools used to conduct security evaluations that are not part of the unit under evaluation shall be studied in isolation to make sure they correctly represent and assess the test assertions they make.

_____**108.** Test tools should also be examined to ensure they do not interfere with the conduct of the test and do not modify or impact the integrity of the product under test in any way.

_____**109.** Laboratories shall have procedures that ensure appropriate configuration of all test equipment.

_____**110.** Laboratories shall maintain records of the configuration of test equipment and all analysis to ensure the suitability of test equipment to perform the desired testing.

_____**111.** For common criteria testing, "traceability" is interpreted to mean that security evaluation activities are traceable to the underlying common criteria requirements and work units in the common evaluation methodology.

_____**112.** Test tools and evaluation methodology demonstrate that the tests they conduct and the test assertions they make are traceable to specific criteria and methodology.

_____**113.** The laboratory shall use documented procedures for sampling.

_____**114.** Whenever sampling is used during an evaluation, the laboratory shall document its sampling strategy, the decision-making process, and the nature of the sample.

_____**115.** Sampling shall be part of the evaluation record.

_____**116.** The laboratory shall protect products under evaluation and calibrated tools from modification, unauthorized access, and use.

_____**117.** The laboratory shall maintain separation between and control over the items from different evaluations, to include the product under evaluation, its platform, peripherals, and documentation.

_____**118.** When the product under evaluation includes software components, the laboratory shall ensure that configuration management mechanisms are in place to prevent inadvertent modifications to the software components during the evaluation process.

_____**119.** The laboratory shall have procedures to ensure proper retention, disposal, or return of software and hardware after the completion of the evaluation.

_____**120.** The laboratory shall have procedures for conducting final review of evaluation results and the laboratory records of the evaluation prior to their submission to the customer.

_____**121.** The laboratory shall issue evaluation reports of its work that accurately, clearly, and unambiguously present the evaluator analysis, test conditions, test setup, test and evaluation results, and all other required information.

_____**122.** Evaluation reports shall provide all necessary information to permit the same or another laboratory to reproduce the evaluation and obtain comparable results.

_____**123.** There may be two types of evaluation reports: (a) reports that are to be submitted, and (b) reports that are produced under contract and intended for use by the customer.

_____**124.** The evaluation report shall contain sufficient information for the exact test conditions and results to be reproduced at a later time if a reexamination or retest is necessary.

_____**125.** Reports intended for use only by the customer shall meet customer laboratory contract obligations and be complete.

_____**126.** The electronic version shall have the same content as the hardcopy version and use an application format (Adobe PDF or Microsoft Word).

_____**127.** Evaluation reports that are delivered in electronic form via electronic mail shall be digitally signed or have a message authentication code applied to ensure integrity of the report and the identity of the laboratory that produced the report.

_____**128.** The laboratory shall provide a secure means of conveying the necessary information for the verification of the signature or the message authentication code.

_____**129.** Confidentiality mechanisms shall be employed to ensure that the evaluation report cannot be disclosed to anyone other than the intended recipient(s).

_____**130.** Each applicant and accredited laboratory shall have written and implemented procedures.

_____**131.** Implementation is used here to mean that the appropriate management system and technical documents have been written, experts and expertise obtained, training conducted, activity conducted, activity audited, and a management review conducted.

_____**132.** Procedures are an integral part of the laboratory management system and shall be included in all aspects of the laboratory operation.

_____**133.** A laboratory shall implement all of the procedures that are required to meet the accreditation requirements.

_____**134.** Failure to have implemented procedures may lead to suspension of accreditation.

_____**135.** General procedures for the following activities are required and shall be implemented before accreditation can be granted:

- _____**a.** Internal audits and management review.
- _____**b.** Writing and implementing procedures.
- _____**c.** Writing and implementing instructions.
- _____**d.** Staff training and individual development plans.
- _____**e.** Contract review.
- _____**f.** Staff members who work at home and at alternate work sites outside the laboratory (telecommuting).
- _____**g.** referencing NVLAP accreditation and use of the NVLAP logo.

_____**136.** The following program-specific procedures shall be implemented before the activity is undertaken; as well as, procedures for writing common methodology work-unit level instructions before an evaluation is conducted:

- _____**a.** Writing a work plan for an evaluation.
- _____**b.** Selecting the members of an evaluation team.
- _____**c.** Writing an Evaluation Technical Report (ETR).
- _____**d.** Writing an Observation Report (OR).
- _____**e.** Conducting an evaluation at a customer's site (if the laboratory offers such services).
- _____**f.** Conducting evaluations: for specific technologies (firewalls, operating systems, biometric devices).
- _____**g.** Vulnerability analysis.
- _____**h.** Conducting independent testing.
- _____**i.** Requesting and incorporating interpretations.
- _____**j.** Working with NIAP or other validators during an evaluation.
- _____**k.** Records and recordkeeping for evaluations.

services and, in the construction of a secure information system, it is the direct responsibility of the security designer to manage the integration between authentication and authorization. This dependency can be automatically implemented by PBM, with strong guarantees about its correct realization.

An important aspect of the design and implementation of a secure information system is the correct consideration of the security principles. They represent fundamental guidelines derived from experience. One of the most well-known security principles is the "least privilege" principle, which claims that elements of a system should only be authorized to execute the minimum set of actions that are required in order to fulfill the specified tasks. A crucial obstacle to realization of this principle is the difficulty in managing security policies. For instance, today most Web applications and Web services use a single account to access the data stored in the database supporting the application, and the presence of a single vulnerability in the Web application may jeopardize the protection of the complete database content. Finer granularity controls and the application of "defense in depth" are services made available by tools for policy-based security management that permit better compliance with the "least privilege" principle.

The realization of policy-based security management has to consider the collection of approaches and solutions offered by current technology. Access control is one of the critical components in the realization of a secure system, and many different models have been proposed to organize and support access control policies. The level of support of the high-level security requirements strongly depends on the features of the access control model that the underlying technological system is able to support. For instance, the high-level requirements can use the concept of "role," in a way consistent with the features of the role-based-access control (RBAC) model, but the underlying system may not offer native support to it; the tool will then be responsible for introducimg a mapping from the high-level RBAC policies to the specific model supported by the system.

Next, the main security objectives are presented. Then, well-known security principles are presented, and for each of them we describe how the realization of a policy-based security management can help achieve them in the realization of a secure information system. Finally, the major access control models are described, and it will be shown how a modern approach for policy-based security management can flexibly support them.

Security Objectives

In computer security, the acronym CIA describes the basic security objectives of *Confidentiality*, *Integrity*, and *Availability*, which a secure system is typically designed to support. These three basic objectives are the basis for realizing a large variety of security functions and satisfying the security requirements of most applications. In some applications there is the need to support only part of them, but a secure system is applicable to concrete scenarios only if all three of them are offered by the system and can be immediately adopted when the need arises.

Confidentiality is the property that is typically associated with the use of encryption. Indeed, when the concern about security derives from the transmission on a channel of sensitive information, encryption represents the crucial technology able to protect the information content of the transferred information from being readable by adversaries who have access to the communication channel. In information systems, the confidentiality of information stored within the system is mostly realized using the access control services, which are responsible for monitoring every access to a protected resource. Only read accesses that are consistent with the policy will be allowed by the system. In some cases, encryption can support the realization of an access control policy for read operations, but this is reserved for information systems with outsourced resources or for representation of data at the low level (hard disks support the encryption of the information contained in them).

Integrity is arguably the most important security service in the design of business applications. Integrity guarantees that all information stored and sent along communication channels is not manipulated by unauthorized users without detection. Integrity in network traffic commonly relies on the use of hash functions, message authentication codes, encryption functions, and digital signatures. Integrity for services requires that the function of the service is not manipulated (supported by code signing) and that only authenticated users that have been authorized to invoke a given service are actually able to have their service requests processed by the system. The critical aspect for achieving integrity protection is that the access policy is configured in a way consistent with the security requirements.

Availability focuses on the resistance against attacks that aim at disrupting the offer of services. This aspect, as a security service, is particularly important for military applications. In the business environment, this is typically considered together with safety and reliability aspects and represents the property that the system is able to continuously provide the services, independently from the variety of threats, due to adversaries or random events that may make the system inoperable. There may be specific business scenarios where the security aspect is extremely relevant (Web application providers that are victims of flooding attacks by adversaries who want to blackmail the service owners), but in most cases the scope is the complete collection of all the possible malfunctions that can block the system.

Beyond confidentiality, integrity, and availability, other services are often added in this classification as basic security services, but they can typically be considered as variants or combinations of the main services. *Authenticity* can be considered a variant of integrity, where resources and services have to prove their origin and users have to prove the control of a specified identity. *Accountability* is also a variant of integrity, where the goal is to guarantee that actions on the system are always recorded without loss and associated with the verified identity of the user. In this way, *nonrepudiability* can also be guaranteed, since users cannot deny that they were responsible for the actions they executed on the system.

Security Principles

Security principles denote the basic guidelines that should be used when designing a secure system. Experience shows that a crucial success factor in the design of a secure system is the correct consideration of the security principles. Vulnerabilities and attacks in most cases can be ascribed to the inadequate application of some principle.

Several classifications of these principles exist. A classical and seminal analysis is the one by Saltzer and Schroeder [23], which lists the following principles: least privilege, economy of mechanism, separation of privilege, psychological acceptability, fail-safe defaults, complete mediation, open design, and least common mechanism.

The *least privilege* principle requires that the set of authorizations that each user gets in the system has to be the minimum set that permits the user to execute his or her role. The same principle can be adopted for the configuration of the privileges of programs and services. The idea is that the *need-to-know* approach has to be used when giving access to resources or services. A critical requirement to correctly apply the principle is to have available an expressive authorization language, which permits a fine-grained definition of the boundaries of the access domain of each user and process. The critical obstacle to the application of this principle, when a flexible access control language is available, is the difficulty to precisely forecast the domain of resources that the user will need to access in the execution of his tasks. The application of PBM offers great support to the realization of this principle, as the policy is specified in a more abstract and structured way and the limitations to the accesses of users can be better delineated. The application of the defense-in-depth approach is a variant of this principle that receives significant support from the advanced support of PBM.

The *economy of mechanism* principle establishes that the protection has to be obtained with a mechanism that is as simple as possible; otherwise it becomes harder to guarantee that the system is able to protect the resource. This principle becomes harder to respect in modern information systems, where resources are typically stored in a layered system. For example, a sensitive credit-card number can be used by an application, which stores it into a database, which stores it into a table stored on a disk managed by an operating system, which may be executed in a virtual machine running in parallel with a multitude of other processes; each layer may offer to the adversary its own opportunities to bypass the protection offered by the application. The protection then depends on the robust implementation at every layer. The use of encryption can mitigate the problem, but its adoption is far from trivial in most circumstances. PBM helps to have a consistent representation of an access policy across the multiple layers, increasing the strength at each layer.

The *separation of privilege* principle clarifies that greater protection can be obtained by requiring distinct actors for the execution of an action. In this way the system is more robust against breaches of trust in the principles legitimately receiving access privileges. An access control model supporting separation of duty constraints supports this principle. PBM can support separation of duty constraints even when the underlying access model does not offer native support to this construct.

The *psychological acceptability* principle states that the security solution has to be understandable by the users, both in its design and during its use. PBM offers clear support to this principle in the design phase, as it offers a way to understand the variety of security configurations that characterize a modern information system.

The *fail-safe defaults* principle suggests the use of a secure default configuration, where in the absence of further information, an access has to be denied. The use of abstract policies can support the system-level specification of default protective actions that will be enforced by all the elements in the system.

The *complete mediation* principle requires that every access to a protected resource must be monitored and verified for consistency with the access policy. The complete coverage of accesses offered by PBM can provide more robust guarantees that each access path is captured by the system.

The *open design* principle establishes that the security of the system must not depend on the obscurity of its design; rather it has to depend on knowledge of a few well-managed secrets. In PBM, the availability of a high-level description of the policy limits the reliance on the assumption that the system can be protected by keeping hidden the protection measures. Instead, modern security practices are promoted.

The *least common mechanism* principle concerns the design of solutions where a single resource or piece of software is used to mediate accesses for different users. Any vulnerability in such an element can then lead to a compromise of the system. PBM helps the realization of

this privilege, as it simplifies the configuration in a consistent way of multiple devices.

Access Control Models

The term *access control* commonly denotes the combination of the authentication, authorization, and auditing services. Each of the three services is organized in two parts: a policy, directing how the system resources should be accessed; and a mechanism, responsible for implementation of the policy. Of the six components, the one that mostly characterizes the access control system is the *authorization policy*.

The authorization policy, given an access request produced by a user with the intention to execute a specific action on a resource, has the goal of specifyin whether or not the request has to be authorized. Many proposals have emerged for representation of the authorization policy. The design of the authorization policy has to carefully balance the requirements of expressivity with the strict efficiency constraints that limit the amount of computational resources that can be dedicated to processing each access request. There are a few long-term trends, clearly visible in the evolution of IT technology, that have a specific impact: The evolution of computer systems is significantly increasing the amount of computational resources available to process an access request; the application of access control increasingly occurs in distributed systems where the delay due to network access can support a more complex evaluation; and application requirements are becoming more complex and require the evaluation of sophisticated conditions. These trends lead to a progressive increase of the amount of resources available to process each access request and to a corresponding enrichment of the access control models used for representation of the authorization policies. We summarize the evolution of these models, describing their main features. Each model typically extends previous proposals and offers specific new functionalities.

The classical access control model, which today is still the basis of most operating systems and databases, is the discretionary access control (DAC) model, which starts from the assumption that users have the ability to manage the information they access without restrictions and users are able to specify the access policy for the resources they create. The access policy can be represented by (Subject, Resource, Action) triples that describe each permitted action. The elements of the policy can be organized by resource (offering access control lists) or by subject (offering capabilities). This access control model presents a number of variants; for instance, a user can transfer the privileges he received; also, programs can be configured to give to users invoking the program the privileges of the owner of the program.

A first evolution of the DAC model was represented by the mandatory access control (MAC) models, which establish policies that restrict the set of operations that users can apply over the resources they are authorized to access. The most famous of these models is the Bell-LaPadula model [24], which has been designed taking inspiration from the approaches used for protecting information in military and intelligence environments, classifying resources according to their secrecy level, and giving users clearances to access resources up to a certain level; restrictions are then imposed on the flow of information. The restrictions guarantee that information will not flow from a high level to a low level, independently of the actions of the users. Alternative MAC models have been defined supporting integrity (the Biba model [25]) and protection of conflict-of-interest requirements (the Chinese Wall model [26]). All these models, when applied on real systems, showed significant shortcomings, mostly due to their rigidity; the presence of covert channels in real systems limited the robustness of the approach. The idea of establishing restrictions on the operations of a resource that depend on properties of resources and users is an advanced aspect that characterizes recent access control solutions.

The role-based access control (RBAC) model [27] assumes that the assignment of privileges to users is mediated by the specification of roles. Roles represent functions in an organization, which require a collection of privileges to execute their tasks. Users are assigned to a role depending on the organizational function that is given to them. The model is particularly interesting for large enterprises, where this structure of the access policy greatly facilitates the management of the security requirements. The evolution of the access policy can be better controlled, with a clear strategy to support the evolution of the required resource privileges and of the organization. The use of roles in general requires two kinds of authorizations: system authorization specifying the privileges a role should acquire and role authorization specifying the subjects that can enact the defined roles. This increase in structural complexity is in most cases mitigated by a significant reduction in the size of the policy and by an easier management. The RBAC model has been successful and has been adopted in many environments, with dedicated support in the SQL3 standard and modern operating systems.

A modern family of solutions is represented by attribute-based access control (ABAC) models. These models assume that authorizations can express conditions on properties of the resource and the subject. For instance, assuming that each resource has an attribute that denotes the identifier of the subject that created the resource, a single authorization can specify the ownership privilege for all the creators of every resource; this would either require an ad-hoc mechanism in the access control

module or the creation of a distinct authorization for every resource. The advantages in terms of flexibility and expressive power of the ABAC model are evident. The main obstacle to its adoption in real systems has always been the worry about the performance impact of such a solution. In the scenario of access control for cooperating Web services, this worry is mitigated by the high cost of each access that makes acceptable the cost required for evaluating predicates on resource ad user properties. The XACML proposal is a notable example of a language that supports an ABAC model. The evolution of access control solutions is expected to lead to a wider adoption of ABAC models.

Another family of authorization models focuses on the specification of the constraint that different users have to be involved in executing a task. This is consistent with the "separation of privilege" principle presented earlier, which urges the design of secure systems to be robust against breaches of trust, by making critical actions only executable with the cooperation of a defined number of distinct users. The classical example is the withdrawal at a bank of an amount larger than a given threshold, which requires the cooperation of a bank teller and the supervision of the branch director. The damage that can be done by a corrupt or blackmailed bank employee is then limited.

Several models have been proposed for representation of these access control restrictions, commonly called Separation of Duty (SoD) constraints. Today the design of such a model typically occurs extending a role-based model, specifying different privileges for roles that are required in the execution of a given process, then imposing that the same subject cannot enact two roles. There are two variants of SoD conflicts: Static SoD and Dynamic SoD. Static SoD assumes that the roles are rigidly assigned to users, who will always enact the same role in every action. Dynamic SoD assumes that the conflict has to be evaluated within the domain of a specific action instance, where distinct users have to enact conflicting roles. The same user may enact conflicting roles, as long as they are enacted in different action instances. Static SoD is the model receiving greater support, typically at the level of policy definition, with the availability of techniques that permit the identification of assignments of privileges to users that may violate the constraint. SAP Access Control, for instance, supports the detection of static SoD conflicts during role design and provisioning. Dynamic SoD requires robust support from the execution system, and this remains a critical requirement. Dynamic SoD requires some robust way to keep track of the history of accesses within an action. An extensive analysis of these issues appears in Chapter 45.

We note again that PBM can offer the opportunity to use a sophisticated high-level policy model for the design of the policy, taking the responsibility for mapping the high-level representation to the concrete access control model that the system responsible for the implementation of the system can offer. This is one advantage of using such an approach. The PoSecCo project, described later in the chapter, offers an abstract flexible policy language, with support for RBAC and ABAC models. This policy can be translated into a collection of policies for the low-level systems that are used in the IT infrastructure, each with its own restrictions. This represents an interesting approach for applying modern access control models in a scenario where common network protocols, operating systems, DBMSs, Web servers, and application servers are used.

To conclude this analysis, we want to quickly present the concept of *obligation*, which presents specific features that clearly distinguish it from the concept of authorization presented above. Obligations are Embedded and Communications Alliance (ECA) policies that serve to determine future actions a subject has to perform (on a target) as a reaction to specific events. As noted by Sloman [28], obligation policies are enforced at the subject, while access control policies are enforced at the resource side. They also differ from the provisional access control model, proposed by Jajodia [29], that extends the traditional yes/no access control answers by saying that subjects must cause a set of conditions to be evaluated to true "prior" to authorize a request. Obligations are used in many management fields such as Quality of Service (increase resources if a SLA is not satisfied), privacy management (delete user information after 6 months), auditing (raise an alarm if some events occur), dynamic network reconfiguration based on security or network events (activate backup links in case of DDoS), and activity scheduling (periodic backups). Complex events can be specified from basic events using event expressions managed also using external monitoring or event services and reused in many policies. Due to their operative and temporal nature, obligations are not only used in security-relevant policies but also for workflow management. Unlike access control, obligations policies are often unenforceable; that is, the system cannot ensure that each obligation will be actually fulfilled by the subject [30]. There is a lack of security controls able to enforce obligations. Even if ad hoc agents have been sometimes proposed [31] and some tool is available, to be practically used, obligation policies are often mapped to other enforceable authorization mechanisms [32].

4. CONTROLS FOR ENFORCING SECURITY POLICIES IN DISTRIBUTED SYSTEMS

The fulfillment of high-level security objectives in distributed systems goes beyond the specification of AC policies and their enforcement, which is typically done at the endpoint (close to the resource that requires protection). Complications that arise in distributed systems result from

the topological arrangement and interaction of system elements over trustworthy and untrustworthy networks. The satisfaction of CIA properties in distributed systems can primarily count on two different categories of security controls. Firewalls that separate network portions with different security levels, provide security checks before allowing incoming and outgoing network traffic, and communication protection mechanisms, like VPNs, that allow two endpoints to securely communicate over untrustworthy networks. Next, the difficulty in choosing the "best" security control in a given context, as well as an alternative firewall and communication protection technologies, is explained in much more detail.

Criteria for Control Selection

As previously described, the plan phase of the security life cycle requires the identification and selection of appropriate security controls. Evaluating the alternatives is, however, not an easy task because different control technologies have different features, performance, management costs, and security implications. First of all, there is a large availability of security controls. They may be available at the endpoints (personal firewalls, channel protection mechanisms), or in the infrastructure (VPN gateways, border firewalls).

Firewalls are displaced in many points of the corporate networks to separate the internal network in portions at different security levels (the administrator's from the guests' subnet). Firewalls have different functionalities, as explained in the next section, which can be used to enforce different policies, but they have different performance. Performance critical elements often run on dedicated appliances, as it often happens for the border firewalls, the main elements of defense as they separate the internal network from the remainder of the (unsecure) Internet. Filtering capabilities are also available at the OS level (iptables in Linux), or they can be freely installed both to be used for host protection (personal firewall) or to implement a filtering mechanism (forwarding firewall). Best-practices suggest discarding unallowed traffic as soon as possible, that is, as close as possible to the source. But other factors need to be carefully considered; for instance, the performance, or the trustworthiness of the control to configure, based on the vendor/product reputation and on an analysis of historical data of vulnerabilities (number, seriousness, exposure time) [33]. As previously anticipated, firewall configurations are an ordered list of rules; the action enforced is the one taken from the first matching rule. Software-based implementations of the resolution algorithm have linear processing time; this means that the higher the number of rules, the higher the overhead and the lower the performance. Therefore, optimizing the rule set is mandatory to have reasonable performance. Hardware-based implementations use expensive hardware and sophisticated algorithms [34] (the Content-Addressable Memories, to improve the performance to a constant time; that is, the firewall takes (more or less) the same time regardless of the rule set size). However, when the hardware resources are saturated, no other rules can be added. For instance, Netscreen 100 products allow the specification of no more than 733 rules. More expensive appliances need to be bought if more rules are needed; thus, in this case, the optimization of the rule set may also reduce the expenses.

The enforcement of a communication protection policy shares the same decisional problems, but it is even worse due to the availability of different technologies working at different levels of the ISO/OSI stack. The most well-known solutions are IPsec, which works at the network layer, the TLS protocol, which works up to the transport layer, and WS-Security, which prescribes how to protect SOAP messages using XML Signature and XML Encryption. In most cases, these protections are available directly in the kernel (IPsec), in the server software (TLS), and in the application containers (WS-Security). Therefore, the decision of the most appropriate one does not depend on the availability but on other considerations, such as the efficiency of the solution, the configuration and management costs, the ease of use for the clients, and the overall security. These technologies can be divided into channel protection, when the protection is applied to data during the transmission and is valid up to the other communication party, and message protection, when the protection is applied to data prior to be transmitted (WS-Security and S/MIME) so that the communication medium becomes irrelevant. The decision between channel and message protection is also very sensitive and requires a careful analysis of the systems to be configured. This difficulty can be exemplified with the help of, for instance, WS-Security. This technology can be used to encrypt sensitive information exchanged by Web services and is considered very secure, as application data remains encrypted along the entire communication channel, whereas application data protected by TLS is often subject to TLS offloading, which results in unencrypted data exchange within a service providers' network. The choice of using WS-Security, however, must consider the potential impact on other security mechanisms in place. It can, for instance, inhibit the work of application-level or content-inspection firewalls. It can also prevent data leakage prevention systems to detect the leakage of sensitive information in outbound calls. Moreover, message protection technologies have worse performance compared to channel protection ones. Figure 23.5 presents the logical view of the techniques available at the different layers together and illustrates the possibility of nesting them. Note that, practically, the implementation of the WS-

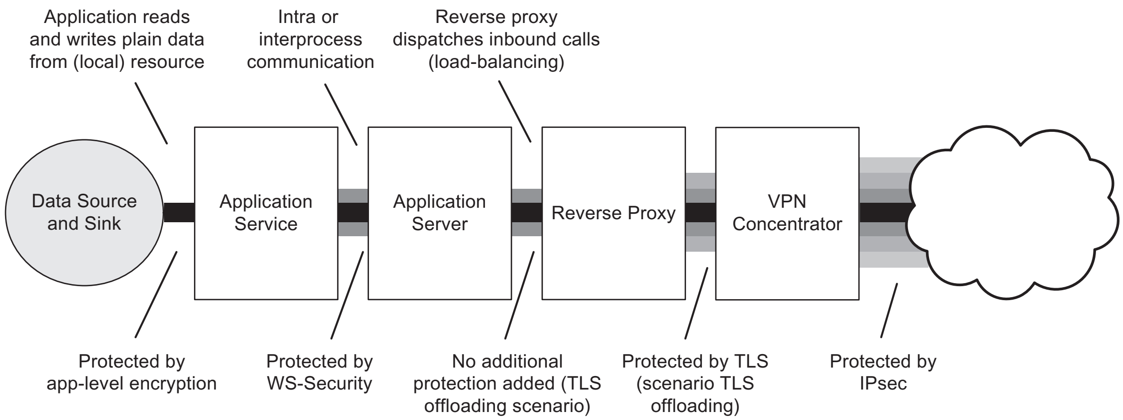

FIGURE 23.5 Logical view of data protection offered by different technologies in Web service environments (scenario SSL offloading).

Security is typically offered by plug-ins or modules of the Application Services (Rampart is the security module of Axis2).

In addition to the above considerations, distributed systems are intrinsically redundant for availability purposes. Together with duplicated functionalities, many backup solutions are available to connect different endpoints, even if they may be disabled. Redundant controls are often used in combinations (configured with the same policy) to mitigate the risk of attacks in case one of the controls has some vulnerability. In other words, one needs not only to decide on (and subsequently configure) the main security controls, but also to have backup solutions that cope with failures or attacks.

Another aspect that complicates the selection of security controls is that they cannot be considered in isolation. In general, every time a security control blocks or alters the information transmitted (changing the addresses), as for NATting and packet enveloping, or the content, like the encrypted communications, there is a risk that another control is hampered; thus, another high-level policy is not enforced.

Other parameters that need to be considered when selecting and configuring security controls are management costs (including the configuration costs), deployment costs, efforts related to the creation of the initial configuration (controls provided with a GUI are often preferred to a script-based approach), or efforts related to implement configuration changes (automatic remote deployment systems are preferred to manual ones). Moreover, the expressiveness of the policy is important. Depending on the layer where each solution works, security controls can decide based on MAC or IP addresses and ports, up to application layer information as users, and roles, or other semantically rich information.

In summary, automatic or semiautomatic tool support would significantly facilitate the selection and evaluation of appropriate security controls and their configuration. The PoSecCo project, for instance, proposes an optimized control selection and configuration generation starting from end-to-end requirements.

Firewall Technologies

An overview of firewall types is given by the NIST in [35]. The simplest firewall feature is *packet filtering*, which makes decisions on each received packet based on information in IP and transport headers. Rules for packet filters are sometimes referred to as five-tuples, as they include conditions on IP source and destination addresses, source and destination ports, and the IP protocol field. Packet filters are very efficient and very often work at wire speed even without dedicated hardware. However, they cannot be used to express complex filtering policies (to allow FTP in passive mode), and in general, compared to more sophisticated firewalls, more rules are needed to specify the same policy. However, many studies proved that their performance is seriously affected by the quality of the rule set. Reducing overlapping rules (that match the same packets) and eliminating redundant ones (never activated rules) [36][37], together with a careful rule reordering based on traffic profile [38], strongly increase the overall performance.

Stateful inspection improves packet filters by tracking connection states at the transport layer by examining certain values of TCP headers and maintaining a *state table*. State values are used to take decisions (allowing all the TCP packets from an "established" (the responses)) or "related" connection (the FTP data connections), or blocking packets that do not comply with the TCP protocol specification. Some controls that implement the stateful inspection are also able to track other protocols (permit DNS response only after DNS query), and ICMP echo-reply only after an echo-request. Stateful inspection may enforce bandwidth control (to limit the number of connections allowed to a given destination, or the packet

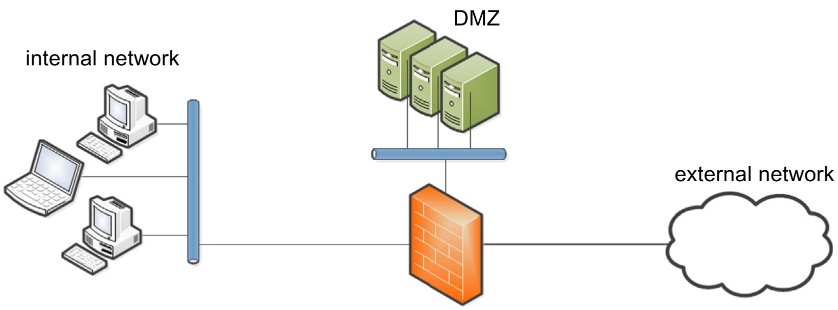

FIGURE 23.6 A screened subnet with a DMZ created using a three-legged firewall.

rate per destination address or port base). Presently, stateful firewalls are the most frequently used technology as they allow sufficiently expressive policies, but they are also appropriate where performance is critical (for border protection) as they are often sold with dedicated hardware appliances. As stated previously, analyzing the rule set and optimizing it allow organizations to save money as less expensive hardware can be bought.

Another capability is the *stateful protocol analysis*, also known as *deep packet inspection*; that is, the ability to read the data and reconstruct the state of application layer protocols. Elements able to perform deep packet inspection are often referred to as *application firewalls*. Due to the large variety of application protocols, these security controls can be "customized" to a specific protocol to perform a more focused analysis; therefore they are named specialized application firewalls, the most widespread being the Web Application Firewall (WAF). The WAF can block traffic depending on the values of HTTP properties and fields (e.g., they can filter email messages that contain attachments of a given type), or block possibly harmful protocol operations, as it is often the case for the FTP "put" command or HTTP unsafe methods (TRACK, TRACE, DELETE). Additionally, application firewalls are able to check traffic compliance to protocol standards or to a set of nonharmful implementations ("RFC compliance") and to identify unexpected sequences of commands. Application firewalls enable fine-grained decisions (to allow or deny access to web pages), not only considering their URLs but also checking whether Java or ActiveX are used, or filter TLS connections from/to endpoints whose certificates have been issued by an untrustworthy certification authority. At the application level, information is often represented in the form of strings (MIME objects, URLs, filenames). For this reason, conditions are often formulated using regular expressions.

An improved type of application firewall is the *application-proxy gateway*, which enforces an access control policy using a proxy agent. It accepts the incoming connections and uses circuit relay services to forward the allowed ones. It hides the details about an internal network, as its address is the only visible one. Additionally, it keeps track of authenticated users, thus permitting the specification of rules that prescribe the maximum number of users allowed, or the maximum number of connections on a per user base. More precisely, the proxy is named "tunneling proxy" if it does not modify requests and responses after a successful authentication, "forward proxy" if it retrieves the resource on behalf of the client (and it belongs to the client's network), and "reverse proxy" if they answer to client requests on behalf of a server or a set of servers (and it belongs to the servers' network). Finally, some firewalls support "*content inspection,*" that is, the ability to analyze and take decisions based on the payload of application protocols.

These components are the bricks needed to create more complex firewall architectures that achieve a better level of protection. For instance, the screened subnet, presented in [39], creates an intermediate level of protection between internal and external networks by creating a demilitarized zone (DMZ), with limited access to the internal network, where the services to be provided to the external network are usually put (see Figure 23.6).

As the firewalls separate network portions at different security levels, they often implement the network address translation (NAT) functionality. NAT is the functionality that changes IP addresses and ports into the received packets. When source IP addresses are modified, the mapping can be one-to-one, if every IP address is statically changed, or many-to-one, when an entire network is mapped on one or a few (public) IP addresses. In the latter case also TCP/UDP port numbers are modified to perform the required multiplexing; for this reason, this technique is named network address and port translation (NAPT). Unlike circuit relay, the NAT does not break the IP stack as the change is made transparently. First proposed to avoid IPv4 address exhaustion, now it is commonly used to hide private networks, but it introduces drawbacks on the connectivity quality and requires careful configuration. On the other end, it can be useful to masquerade the actual IP address of publicly available services or when load balancing systems are used, that forward requests on a pool of services. In that case, the destination NAT is used. For Web servers and Web services, another technique is used that permits associating the resources with URLs in a dynamic way, both to

expose "fancy URLs" usable by the search engines and to redirect content.

Although the importance of a correct configuration of filtering devices is easily understood for the security of the internal network, a "polite" configuration of firewalls can produce a significant impact on the security of the entire Internet. To this purpose, two best-practices have been proposed: *ingress filtering* and *egress filtering*. Ingress filtering is a technique that consists in accepting packets from the outside only if they actually come from the networks that they claim to be from. According to RFC 2827 [40], a systematic ingress filtering starting at the periphery of the Internet would reduce or permit mapping DDoS attacks. Packet filtering at source IP level is usually enough to enforce it. Egress filtering consists in configuring the filtering infrastructure to block the unauthorized or malicious traffic from the internal network. It can be implemented using a packet filter that verifies that the source IP address in all packets is within the allocated IP block used by the company, or in more advanced ways using proxies that authenticate users before allowing them to access the Internet.

Channel and Message Protection Technologies

This part of the chapter presents two channel protection technologies: IPsec, which works at layer 3, and the TLS protocol, which works at layer 4, and two message protection technologies, WS-security, which protects SOAP objects (used by Web services), and S/MIME, which protects MIME email messages. IPsec is a suite of protocols that offers various security services for traffic at the IP layer, for both the IPv4 and IPv6 protocols. The protection is guaranteed by means of two security protocols, the Authentication Header (AH) and the Encapsulating Security Payload (ESP). AH guarantees the integrity and symmetric authentication of IP packets; both the payload and the nonvariable fields of the header. ESP may provide the integrity, authentication, and confidentiality of IP packets payload (but not of the header). Both optionally provide an anti-replay service by maintaining a window with the last 32 or 64 packets. These protocols can be used in two modes: *transport mode* and *tunnel mode*. The transport mode is between two network nodes to provide security services to upper layers and therefore protects only the payload. This type of configuration is named end-to-end security (see Figure 23.7(a). In tunnel mode, a secure channel is established between two endpoints, the gateways, each one associated with the IP addresses of the subnet they control. When packets arrive at one gateway from a subnet and are directed to the other one, they are first encapsulated in a new packet exchanged between the gateways (by means of IP in IP); then its payload (that is, the entire original packet) is protected. This type of configuration is named basic VPN (see Figure 23.7c). Additionally, IPsec in tunnel mode can be used to secure the remote access (to allow a user to connect to a gateway without knowing his IP address a priori via user-level authentication), as shown in Figure 23.7(b). The connections to protect are specified by means of a Security Policy, stored in the Security Policy Database (SPDB). The details to protect a connection are summarized by means of a Security Association (SA). An SA is a univocally identified set of parameters that characterize a unidirectional connection, including symmetric cryptographic

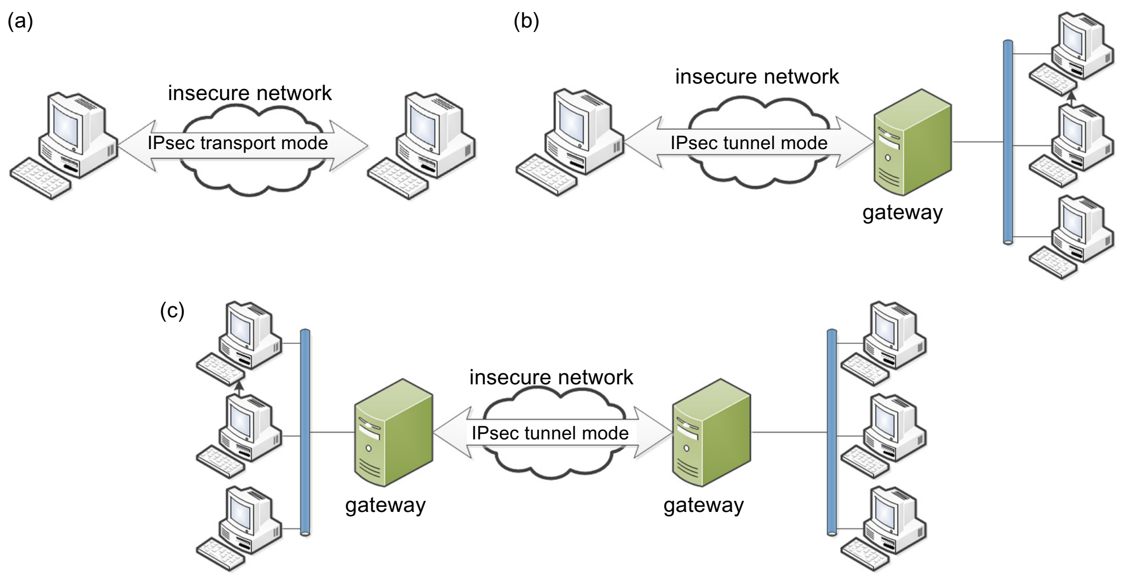

FIGURE 23.7 IPsec.

algorithms, keys, the selected protocol (AH or ESP), and a lifetime. The SA can be manually written by administrators or negotiated using an ad-hoc key management solution, the Internet Key Exchange (IKE) protocol [41], and are stored in a Security Association Database (SADB). A prior offline agreement is needed to write or negotiate the SA and configure IPsec accordingly. In some cases, vendors provide software for simplified remote client configuration (CISCO VPN client). In general IPsec has good performance but it has high management costs. IKE supports certificate-based user authentication; a very granular policy can be enforced.

Transport Layer Security (TLS) is a suite of protocols that allow a client and a server to authenticate each other, to negotiate the security services to enforce, and the cryptographic keys before starting to exchange data at the application layer in a client-server scenario. It was first issued by Netscape as Secure Socket Layer (SSL), then absorbed with minor (but security relevant) revisions by the IETF as Transport Layer Security [42]. TLS works at the transport layer; that is, it is encapsulated in a reliable transport protocol, like TCP. Additionally, there exists the Datagram TLS (DTLS) that guarantees the same security properties with datagram protocols, like UDP [43] and DCCP [44]. The protection is summarized using a cipher suite, a string that indicates the peer authentication and key exchange algorithm, the hash algorithm used to calculate the message authentication code (HMAC for TLS, keyed digest for SSL), and the encryption algorithm (TLS RSA WITH AES 128 CBC SHA). The cipher suites are negotiated using the TLS Handshake Protocol, which also supports server authentication using X.509 certificates. It optionally supports server-requested client authentication. As the TLS Handshake Protocol is very expensive both computationally and in terms of exchanged data, there exists a resume functionality based on a session identification mechanism. The protection is applied to application data by the TLS Record Protocol, which divides in blocks the application data to protect, optionally compresses it, calculates the message authentication code, ciphers, and adds the TLS record header before transmitting each block. The main advantage of TLS over IPsec is that it requires less configuration effort at the client side, as the TLS client is available in every browser together with a list of trusted certification authorities. Nevertheless, its performance is a little worse [45]. For remote access, TLS VPN permits two types of usage: the clientless approach, when an authenticated user can select a set of predefined resources from a Web page, or the thin client, when by means of an ActiveX- or Java-based plug-in an authenticated user can run other applications across the VPN. However, TLS VPNs are subject to other security issues; for instance, as they allow a Web-based approach, they are more vulnerable to password cracking attacks, they may be the vector for malware to the internal network, and, if split tunneling is used, they may allow a compromised remote machine to become a router for the internal network. Additionally, they may increase the risk exposure due to keystroke loggers, open sessions, or cached data on shared machines, as they easily allow anywhere connections also from public machines.

As anticipated previously, when there is the risk of offloading— for instance, in the case of email systems where relaying servers temporarily store the emails before forwarding them to the user's inbox—channel protection solutions working at network and transport layer are not enough. In fact, the assumption that all the intermediaries and the endpoint are trusted does not hold any more. In this case, the protection needs to be applied directly to the exchanged messages. The emails, represented with the MIME format, are protected with the Secure/MIME (S/MIME) [46]. S/MIME applies sender's authentication, message integrity, nonrepudiation of origin, privacy, and data security using X.509 certificates. S/MIME protected messages are conveyed using an ad-hoc MIME type, the application/pkcs7-mime. There are two types of protected messages for security purposes: the "enveloped-data," when data are ciphered with a session key that is then encrypted with the public keys taken from the certificates of all the recipients, and the "signed-data," when data are signed with the private key of the sender's certificate. Message protections can be nested in any order; however, the available implementations include the enveloped-only, signed-only, or signed-then-enveloped messages. S/MIME messages are represented using the Cryptographic Message Syntax format [47], an extension of PKCS#7.

Analogously, in the case of Web services, a SOAP-level security mechanism has been made available, the Web Service Security (WS-Security or WSS). It has been defined as a SOAP extension protocol that specifies how to sign or encrypt messages using XML Signature and XML Encryption. Additionally, it can be used to transport credentials (like X.509 certificates) and security tokens (like SAML assertions or Kerberos tokens) that can also be associated with messages. WS-Security can be used to enforce an end-to-end security at the application layer when Web services are used. Using WS-Security is computationally expensive due to the use of cryptographic algorithms, and it increases the size of the messages. Compared to TLS or IPsec, it is significantly less performing, but it allows for more granular application of the protection, as it can be applied to single XML fields and for the enforcement of more sophisticated authentication and authorization policies. Due to the granularity of the enforcement, configuring and managing changes with WS-Security may require significantly more effort than channel protection techniques, thus posing a major burden to administrators.

5. PRODUCTS AND TECHNOLOGIES

This section introduces a small and diverse selection of mature technologies and products related to PBM, which can now be used to improve system security and compliance. Note that none of them takes a holistic view of PBM. Instead, each example looks at different facets of system security and works with different abstraction levels of security policy. The solutions from SAP, Microsoft, and CISCO exemplify the state of the art in managing authorizations for enterprise applications, endpoint security, and network security devices, respectively. XACML has been selected as an example for policy specification languages, herewith acknowledging its increasing adoption by industry. Moreover, it has been specifically created for dealing with access control, while other languages such as Ponder or CIM-SPL are general-purpose languages. Finally, SELinux is a prominent open-source example for the policy-based configuration of operating systems.

SAP Access Control

SAP access control is an enterprise software application that enables organizations to control access and prevent fraud across enterprise applications, while minimizing the time and cost of compliance. The solution is centered on a repository of access and authorization-based risks related to single or multiple functions executed in the course of business processes. Each business function is linked to one or several actions that implement the respective functionality in a given enterprise application. Users can specify their own risk rules or rely on a standard rule set for business processes implemented by standard ERP applications from SAP, Oracle, and others. A typical SoD risk related to the business process Procure-to-Pay is, for instance, that single users within the same organizational unit have permission to both maintain vendor master data and initiate payment runs, which could be misused to perform fraud (cf. Figure 23.8).

The rule set is the basis for the analysis and reporting of risks caused by the assignment of authorizations to roles and users, performed at the design and, respectively, runtime of an enterprisewide authorization concept. At design time, SAP access control supports the management of roles from multiple SAP or non-SAP systems with a single unified role repository; any new or changed role is subject to risk analysis in order to prevent SoD violations within a single role. Role design is further supported by approval workflows, role refinement according to organizational hierarchies, and eventually results in the automated generation and deployment of technical roles in the respective target application. At runtime, risk analysis is performed during (de)provisioning workflows in order to detect SoD violations that could result from the assignment of multiple roles to a given user. Such workflows are triggered by HR events (as a result of a new hire) or self-services, include approval steps, and eventually result in the automated provisioning of roles (and identities) to all systems concerned.

SAP access control focuses on the design and operation of authorization concepts for the application layer. The definition of risks and, subsequently, roles is rather subject to the design phase of a security concept, while the mapping of generic business functions to the respective applications and authorizations as well as the support of change and provisioning workflows belongs to the implementation and operations phases. With regard to policy abstraction levels, one can distinguish abstract and application-independent business functions and roles on the one hand, and the concrete and application-specific counterparts on the other hand.

Microsoft Group Policy

Microsoft Group Policy is a technology that facilitates the management of configuration settings in Windows

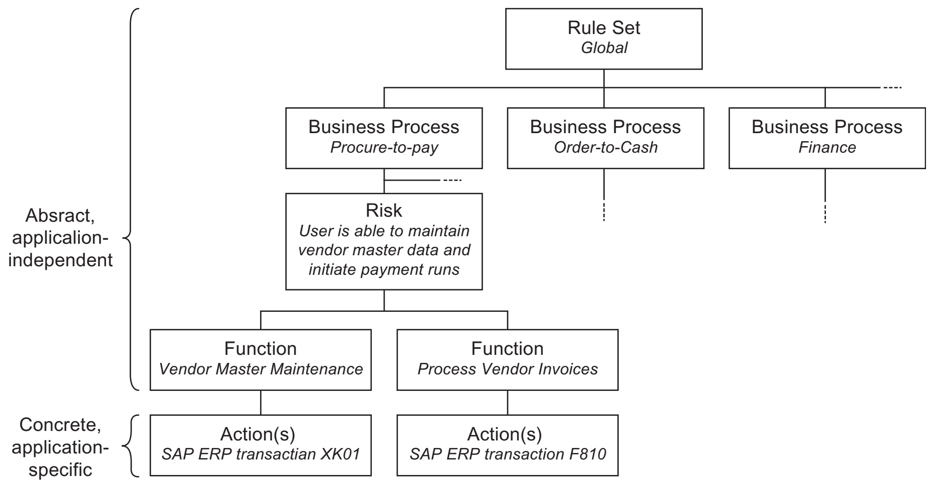

FIGURE 23.8 Example risk specified in SAP access control.

environments. More specifically, domain-based Group Policy supports centralized configuration management and scales up to IT networks that span across multiple sites and domains, thereby relying on Active Directory Domain Services (AD DS).

Although it can be used for configuring all kinds of features, Group Policy is particularly useful for the enforcement of security policies concerning password policies or the setup of endpoint firewalls. Settings governed by Group Policy cannot be modified by standard users, which ensures that security-relevant settings remain as specified and cannot be changed advertently or inadvertently. Technically, a so-called Group Policy Object (GPO) comprises policy settings, each of these prescribing a desired value for a given software configuration parameter. GPOs are linked to a hierarchy of domains, sites, and organizational units in order to determine to which systems and users a GPO shall apply (cf. Figure 23.9). The settings are deployed in regular intervals and manifest primarily in the Windows registry. Group Policy supports inheritance, whereby more specific GPOs prevail over GPOs that are linked to upper-level hierarchy nodes. Policy settings that concern systems are applied after startup, while user-related settings apply after logon.

Figure 23.9 displays the Group Policy Management Console, which administrators use to associate GPOs with hierarchy elements. The Default Domain Policy, for instance, is a GPO associated with the entire company domain, which renders the contained policy settings applicable to all users and systems in the entire domain. On the right-hand side, it becomes visible that this GPO comprises mainly security-related settings (the minimum password length as specified in the registry). While settings can be maintained with the help of the Group Policy Management Editor, further tools extend Group Policy with regard to approval workflows, delegation, or role-based administration.

With regard to the notion of policy abstraction levels, it shall be noted that Group Policy does not support the specification of high-level policies, but works on the level of concrete and software-specific configuration parameters that determine the behavior of a given software feature.

CISCO

CISCO, a leading provider of computer network hardware, offers products to enforce, manage, and monitor the security of network infrastructures for clouds, data centers, and in general for medium to large enterprise networks. It sells a set of modular appliances for network security, including the ASA series (Adaptive Security Appliances), the Catalyst series, and the IOS series, that can be expanded with firewalls (stateful, application layer and content inspection), IPsec- and TLS-based VPN components, and intrusion prevention systems, to scale and reach the company needs. These tools also permit the dynamic definition of zones to partition the network according to security levels (to create the DMZs) and the definition of NAT rules. It also freely provides VPN clients to allow remote access to IPsec VPNs.

All the CISCO devices can be configured using a command-line script-based approach, which they themselves declared as "cumbersome" [48]. For this reason, they

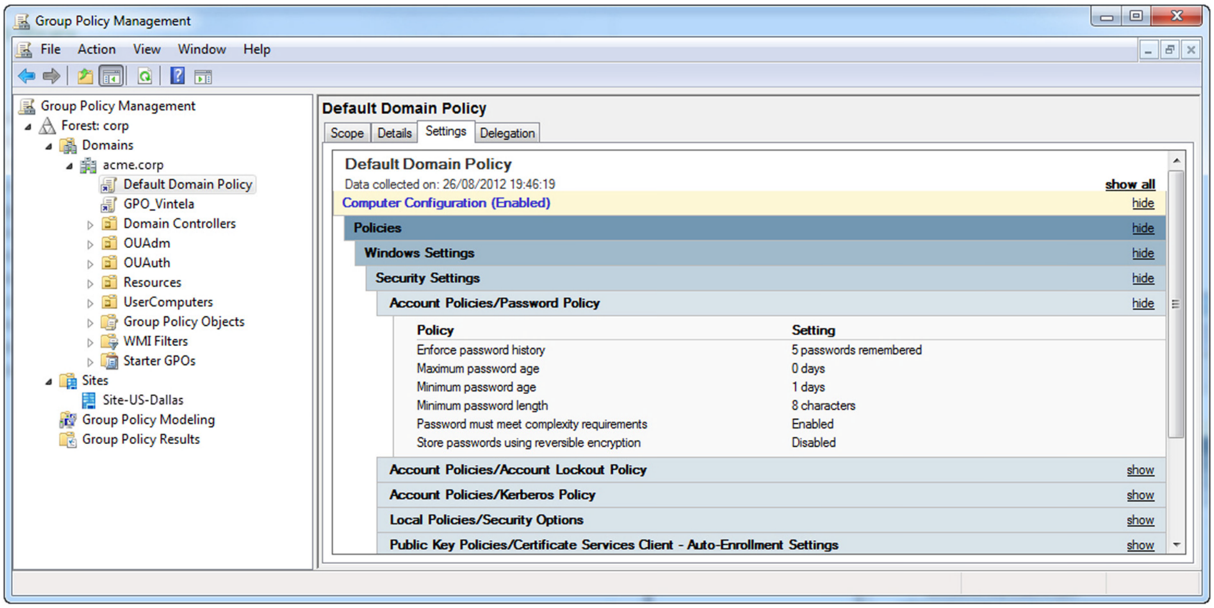

FIGURE 23.9 Microsoft Group Policy Management Console.

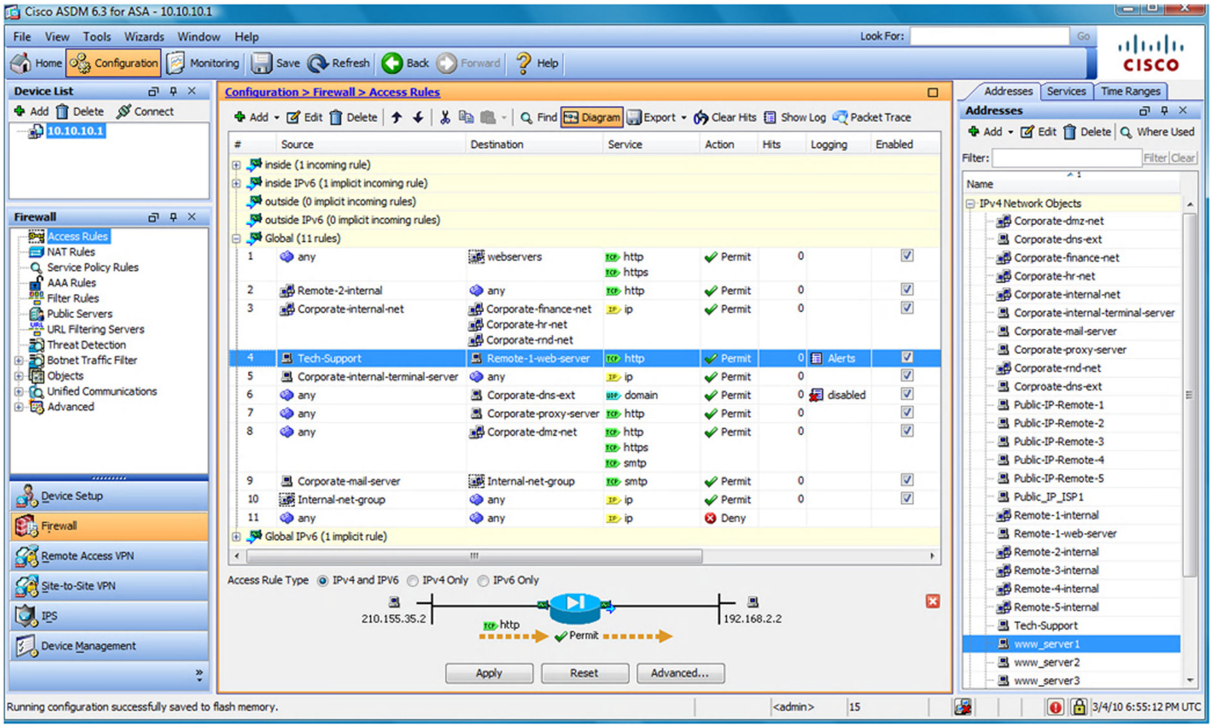

FIGURE 23.10 The CISCO ASDM GUI-based firewall appliance management.

also provide Web-based or stand-alone user-friendly applications that allow administrators to simplify the configuration, troubleshooting, and central management of appliances. For instance, the Adaptive Security Device Manager (ASDM), with a representative interface presented in Figure 23.10, provides setup wizards and administration tools, together with dashboards that provide an at-a-glance view of appliance status, and debugging tools such as packet trace and packet capture. Alternatively, the Cisco Security Manager (CSM) provides a set of tools to perform policy deployment and enforcement in larger environments. Another example is the Easy VPN that allows the central management (and pushing) of channel protection configurations through an Easy VPN server. These tools only cover CISCO appliances and cannot be used with products of other vendors or open-source products.[8]

CISCO products efficiently cover demands for the traditional administration of policies at the lowest abstraction layer, that is, the Executable Policy Layer,[9] with some features of the upper layer, the Concrete Policy Layer. Thus, a policy, in this context, is a collection of rules to configure Cisco appliances, graphically represented in a GUI or represented as a collection of command-line instructions. Human errors and inconsistencies, the leading factor to move toward a PBM approach, may be reduced because of a more efficient data representation and management (the reuse of low-level security rules and objects (IP addresses, ports, and URLs)), because of the availability of simple integrated debugging tools, such as packet capture, ping, and traceroute, or because of the integration with intrusion prevention systems. However, high-level specifications are not supported. Today this status is common to all the companies producing security appliances.

XACML

The eXtensible Access Control Model Language (XACML) is the outcome of the work of an OASIS committee. The XACML Committee released version 1.0 in 2003 [50]. Version 3.0 or higher is expected to be approved in 2013. The goal of the language is to define an XML representation of access control policies, focusing on the description of authorizations.

The main goal of XACML is to offer a platform-independent representation of access control policies in order to facilitate the representation and exchange among systems of the access control restrictions that systems have to apply. XACML is a member of a large family of specifications that

8. A step toward the multiproduct multivendor management of security controls is Firewall Builder [49], which permits support of CISCO devices as well as other open-source firewalls such as iptables and pf with a single GUI and a set of translation and deployment scripts.

9. *Source:*http://www.cisco.com/en/US/products/ps6121/index.html.

offer an XML schema for the portable representation of information to be shared in a distributed system.

The model behind the language assumes that the basic building block is a rule, which is associated with a resource, a subject, and an action. Rules are structured in policies, and policies build policy sets. The specification of the elements of the rules and policies can use the XPath language, supporting the representation of flexible predicates on resource and subject properties. Based on this, XACML can be considered an example of an ABAC model, with the possibility of defining compact policies. This choice is consistent with the general architecture of a policy management system described in Figure 23.3, with the roles of PEP, PDP, PIP, and PAP.

XACML can be considered a successful initiative, with a lot of interest dedicated to it in the research and industrial community. Systems exist that are able to evaluate XACML policies and implement the components of the XACML architecture; many prototypes have been built that use a variant of XACML to manage advanced policies (for obligations, delegations, privacy profiles [51]). The most significant industrial use of XACML today is to offer a representation of the internal policies of a system in a format that can be understood by other components. A very interesting opportunity is the realization of a family of adapters able to create, starting from an XACML policy, the access control configuration of a real system. The XACML Committee has worked on the definition of a variety of profiles that define restrictions and introduce terms for the definition of polices that make them processable by automatic tools. Currently, however, there is only support for a limited number of systems. An interesting profile is the one for the representation of RBAC policies [52].

The XACML language has an interesting role in the design of a PBM system, as it can be used to represent policies in a portable way, using the services of ad-hoc translators to map the XACML policy to the concrete implementation. Also, the ability of some profiles to map a high-level view of the policy to the concrete setting is consistent with the goals of the approach advocated in this chapter. It is not clear whether XACML will emerge as the central component for the realization of such architectures, but certainly it deserves careful consideration in this area.

SELinux

Security Enhanced Linux (SELinux) is the outcome of a project initially sponsored by the National Security Agency aiming at improving the protection of the Linux operating system, with a first implementation made available in 2000. The module was initially offered as a default option in a few distributions, and, since version 2.6 or higher of the Linux kernel, SELinux is a stable part of the operating system.

SELinux enriches the native discretionary model that characterizes Unix-like operating systems. Limitations of this model have been known for a long time and SELinux introduced an additional layer of protection. The approach took inspiration from classical mandatory models and looked at the experience in the use of these models. This led to an offer of higher expressivity and the possibility of flexibly controlling the behavior of the system. Initial experience in the use of SELinux demonstrated the difficulty of putting an additional layer of access control in an existing system: Users encountered frequent situations where the new access control services were blocking the execution of legitimate applications. Progressively, the technology has evolved, and the policies have been greatly refined. Today the presence of SELinux in a system that only uses standard applications and modules does not exhibit anomalies, at the same time offering increased protection against misuse.

The approach used by SELinux relies on the idea of associating a context with three components (role, user name, and domain) to users and processes of the system. Labels with the same structure are assigned to resources in the system. Processes typically inherit the context of the user that invoked the process, except when an explicit policy rule permits change of the running context. A policy defines the compatibility rules among contexts and labels. Typically, processes are only authorized to access resources characterized by a label compatible with the process context (in the same domain). Specific resources that may need to be accessed by a variety of processes will be associated with less restrictive rules. In general, the SELinux policy permits building a rigid compartmentalization among the resources of a system, greatly limiting the possibility that a vulnerability in some process or protocol would lead to the manipulation of a critical resource and the consequent compromise of the system.

An interesting feature of SELinux is the way the policy is defined and applied. A policy language is used to express the policy that a system must follow. Tools are also offered that assist the administrator in the design of the policy. The policy is then compiled, a low-level configuration is produced, and each element is then associated with the resources that will be protected. The compilation phase is introduced to improve the performance and to distribute the policy to all the elements of the system responsible for the protection. This approach is consistent with the idea of using a high-level representation of the policy valid for the whole system, which is then mapped to a low-level configuration to realize its objectives. This can be considered a realization at the level of a single system of the PBM approach, which has as its goal the security management of distributed

systems. The success of SELinux can be considered a valid demonstration of the advantages of such an approach. Recently, the SEAndroid initiative has started, which aims at improving the security of the Android environment with the adaptation of the SELinux approach to it.

6. RESEARCH PROJECTS

Policies and policy-based management has been a research topic for several decades, and, due to its ambition as well as technological advancements, will remain so for a number of years. This section introduces the approach of two public-funded projects to PBM. First, we will introduce Ponder, a project conducted in the early 1990s that is considered a forerunner in the use of policies for system management. Second, we will describe PoSecCo, a project started in 2010, which looks at optimization problems related to policy refinement, the embedding of PBM into organizational processes, as well as policy-based audits. One important difference between the two is that Ponder relies on agents to enforce (AC) policies, while PoSecCo discovers and uses standard security capabilities available in virtually every given system.

Ponder

Ponder is a generic policy framework that was developed by the Policy Research Group of Imperial College in London. It features a policy specification language [28] and a toolkit with a management console tool for dynamically managing policies using policy enforcement agents. Its goal is to support security and management policy specification in large-scale distributed systems.

The Ponder language is *declarative* and *object-oriented*. Everything is represented by an object interface, and policies are written in terms of interface methods. It includes grouping constructs and policy inheritance useful for scalability purposes in large systems. The basic policy types in Ponder are (positive and negative) authorization, refrain, obligation, and delegation policies. Meta-policies are also supported to constrain the acceptable types of policies in the system. Policies can be specified directly as instances or as reusable parameterized template-like policy types from which multiple instances can be created by passing the actual parameters.

In Ponder, administrators create and edit policies using an administration tool. The administration tool includes a policy compiler that transforms the policies to policy classes that are stored in a policy server that acts as a central point of management. Policies can be loaded, unloaded, enabled, and disabled. The description of the system to manage is made using *domains*. A domain is a filesystem-like hierarchy that is used to group objects such as users, resources, services, and devices into categories for management purposes with parent−children policy propagation methods. A *domain service* keeps track of objects in the domain hierarchy and is responsible for evaluating policy subject and target sets at runtime. As domains change dynamically, the domain server maintains the references to all the installed policies that apply to each subdomain. When the domain hierarchy changes, the relevant policy objects are notified of the change.

The enforcement is left to a set of enforcement agents. When policies are loaded, policy objects distribute enforcement classes to the enforcement agents, which are destroyed when policies are unloaded. On the other hand, the enforcement classes react to enable and disable events. In case of authorization policies, the enforcement agent is the access controller of the target object, and for obligation and refrain policies, it is the subject policy management agent. Policy management agents of obligation policies register themselves to receive certain events from the *event server* that collects system events and notifies the registered event subscribers so that obligation policies can be triggered. The Ponder architecture is sketched in Figure 23.11.

Ponder presented some limitation on flexibility due to the centralized management of the enforcement. For this reason, Ponder2 has been developed. Ponder2 provides a new framework for an event-based enforcement wherein management services implement self-management cells that interact with each other through asynchronous events. It comprises an API, a shell that can be used to perform various maintenance actions, and a compiler/interpreter for PonderTalk, the Ponder2 management and policy specification language based on SmallTalk. Ponder2 inherits from its ancestor the authorization and obligation policy models, but it acts differently by giving more emphasis to

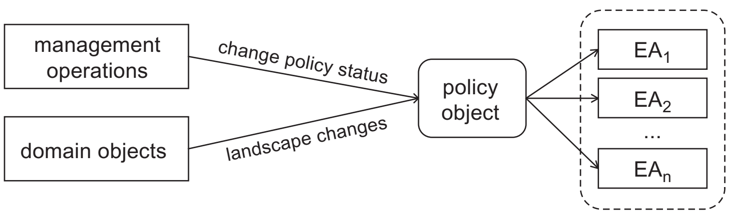

FIGURE 23.11 Ponder reference architecture.

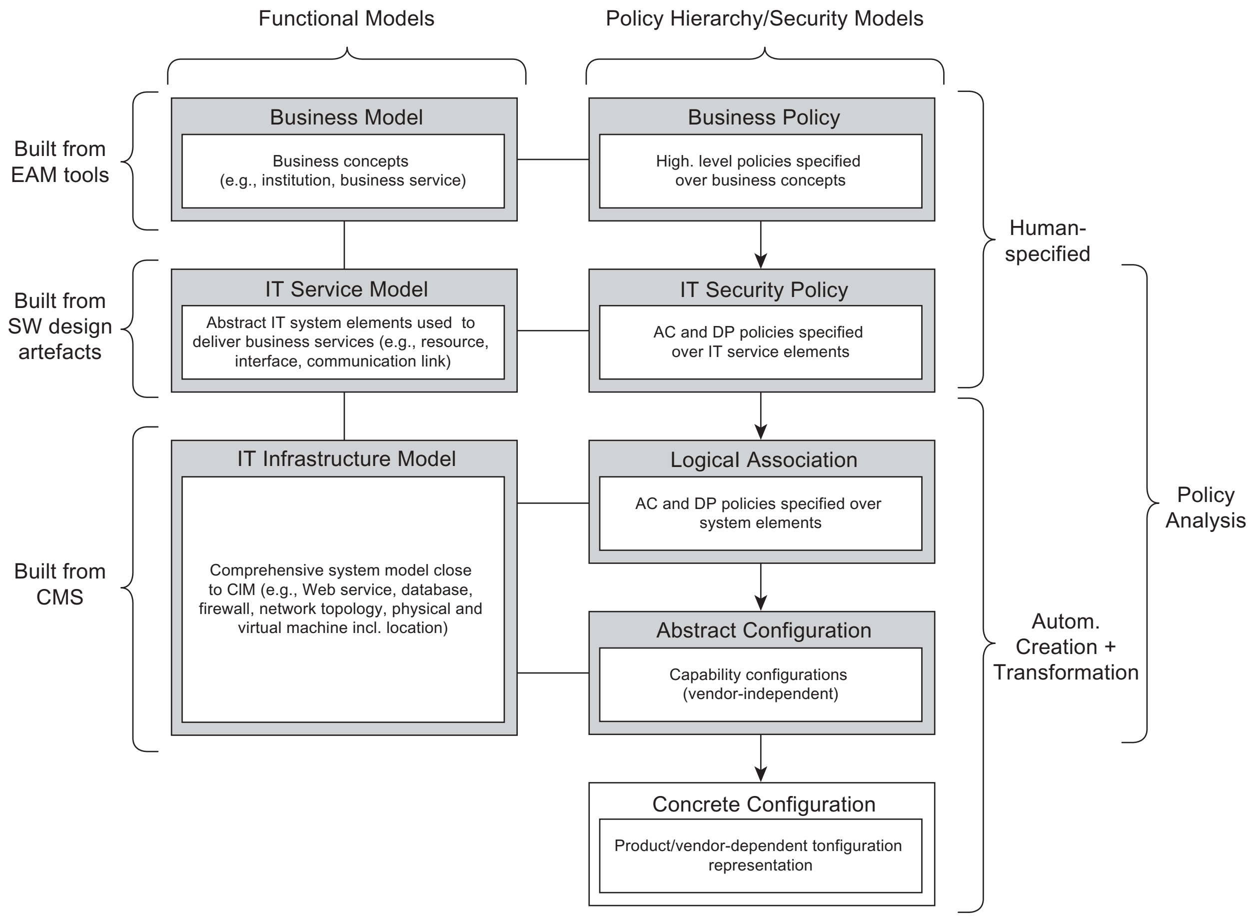

FIGURE 23.12 PoSecCo system and security models.

the dynamic aspects of a system. For example, it supports changes, activation, and deactivation of policies while the system is running, without requiring the system to stop.

PoSecCo

The research project PoSecCo[10] focuses on securing shared IT systems that are used by service providers to deliver to end-users business (application) services, which consist of elements that are in parts operated internally and in other parts provided by outsourcing or cloud providers. Since the project relies on off-the-shelf security capabilities (for enforcing security policies), rather than developing new kinds of policy enforcement points, it bridges the gap between policy-related research and purist policy systems on the one hand, and today's IT systems and management practice on the other hand. This approach aims at rendering research results more applicable to real-world systems and is accompanied by the consideration of economic and organizational considerations around the design and runtime of a security concept.

System and Security Model

The policy hierarchy of PoSecCo consists of five layers, four of which correspond to different abstraction levels linked to a functional counterpart, while the fifth represents concrete configuration information for security mechanisms. Figure 23.12 visualizes the relationships between functional and security models belonging to the different abstraction levels and also mentions how each of the models is built.

A *Business policy* represents a high-level requirement provided by management or stemming from laws, regulations, or customers. Business policies are associated with risks that express the probability of a threat to negatively impact assets or asset classes [53]. The latter are generic concepts that can be linked to arbitrary elements of the *Business Model*, which in turn comprises general business concepts relevant for organizations (institution, business service, customer, organizational role, business information).

10. Policy and Security Configuration Management (http://www.posecco.eu).

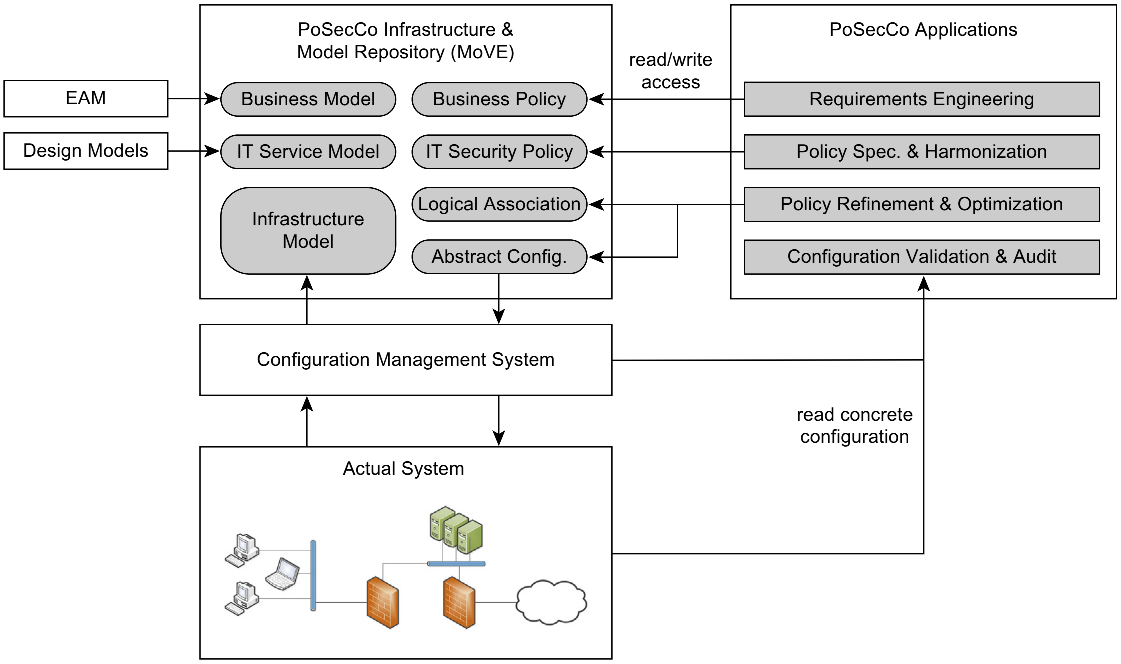

FIGURE 23.13 PoSecCo architecture.

Business policies have a defined structure and can be organized in a hierarchy, but its core is represented in natural language. Business policies are typically created by business and legal stakeholders (management or data protection officers). There exists no dedicated policy language for representing business policies, and the semiformal nature of business policies hampers automated reasoning.

An *IT security policy* represents an Access Control or Data Protection (DP) policy that contributes to the fulfillment of one or several business policies. They are specified over concepts of the *IT Service Model*, which describes the interaction of logical IT resources in order to realize a given business service. Logical IT resources abstract software components present in an actual system, which allows the specification of security policies without considering implementation details. IT security policies are again specified by humans, in particular by security architects, who have the required knowledge to specify appropriate AC or DP policies. IT security policies (as well as lower-level policy representations) are represented by means of an ontology (OWL-DL), which allows the automation of reasoning tasks (conflict or enforceability analysis).

A *Logical association* specifies a security property over two system elements that represent endpoints of a communication link. As such, they refine an IT security policy to the level of the real system, which is described by the *Infrastructure Model*. This topology-aware representation of an IT Security Policy represents the basis for the search and selection of security capabilities that are suitable for enforcing a given policy. A policy demanding a "secure channel" between two communication endpoints, for instance, can be enforced by several capabilities offered "along the way" (the capability of VPN concentrators to establish a VPN connection), or the capability of an application server to support SSL/TLS. The refinement to logical associations and the discovery of suitable enforcement mechanisms is again done with the help of an ontology. Every security mechanism found is then assessed by performance, cost, and security functions that aim at choosing the "best" alternative.

Once a human chooses one (or several) of the security mechanisms proposed for implementation, a so-called abstract configuration is created, which configures a capability in a vendor and product-independent manner. The abstract configuration again gets transformed into a concrete configuration that is understood by the device offering the respective capability. Its representation or format is hence determined by the respective system element.

The policy hierarchy is constructed during the *Plan* and *Do* phases of the classical security life cycle and terminates with the deployment of concrete configurations. The hierarchy will then be used to deal with ongoing requirement and system changes at operations time.

System architecture. The PoSecCo architecture (cf. Figure 23.13) is centered on a model repository called MoVE,[11] which has been chosen to manage all functional and security models. Each of them is stored and versioned independently of each other, but related concepts can be

11. Model Versioning and Evolution (http://move.q-e.at/).

associated by cross-model links. The model repository offers a coarse-grained XMI interface for reading and writing entire models, as well as fine-grained create, read, update and delete (CRUD) operations for the manipulation of single-model elements. Moreover, it supports the definition of state-machines for single classes, whereby state changes result in corresponding events that can be used to trigger other actions. Finally, MoVE offers an OCL interface to query the models.

The business and IT service models of PoSecCo are created by interfacing Enterprise Architecture Management (EAM) systems and by reading software design artifacts (UML component diagrams). The infrastructure model is built by using the WBEM standards from DMTF to read information from Configuration Management Systems (CMS). Such tools represent an important building block of ITIL and commonly support CIM, which is in large part equivalent to the PoSecCo infrastructure model. CMS are also expected to transform and deploy the abstract configuration as soon as it has been completed at the end of the policy refinement process.

The policy hierarchy will then be constructed by so-called *PoSecCo applications* in a top-down manner, each of them using the MoVE API to read and manipulate model elements of its respective abstraction layer. The orchestration of these applications in the course of the plan and implementation phases of the security life cycle is realized by means of an event bus.[12] The change of policies on each abstraction layer results in state transitions that on the one hand persist in MoVE, and on the other hand are published to topics to which other PoSecCo applications can subscribe. The successful harmonization of IT policies by the application of *Policy Specification and Harmonization*, for instance, leads to a state transition from *UNVERIFIED* to *VERIFIED*, which is notified to the application *Policy Refinement and Optimization* for the continuation of the policy refinement.

Requirements Engineering

This PoSecCo application offers a Web-based environment for the specification, management, and monitoring of hierarchically organized security requirements (business policies in terms of PoSecCo). Requirements can be linked to various stakeholders within an organization as to express responsibility, accountability, or interest, which allows tying the hierarchy of requirements to the organizational structure. Different fulfillment models allow specifying under which conditions a requirement is considered fulfilled, partially fulfilled or not fulfilled, and whether such state changes can happen in an automated fashion or require human confirmation (which is limited in time as to force the continuous revalidation of requirements). Furthermore, different reporting views allow users to monitor requirements as to see the compliance rate of organizational units with given laws or regulations.

Policy Specification and Harmonization

This application offers the administrator access to the set of requirements specified in the previous phase and supports him or her in constructing a collection of instances of the IT Security Policy model able to represent the requirements. The IT Security Policy model focuses on the representation of access control and data protection requirements. The access control part supports the high-level formal description of the authentication and authorization profiles of applications.

For the authentication profile, the model considers the description of a variety of authentication techniques. The most common solution is the use of usernames and passwords, but richer solutions based on certificates, hardware tokens, and cryptographic credentials are supported. The model distinguishes between “direct” authentication solutions, where the system managing the authentication phase and verifying the correctness of the claimed identity of the user is the same that will offer the services, and “indirect” authentication solutions, where some support is received by external systems, responsible for the secure retrieval of the protected credential for the complete execution of the authentication phase.

For the authorization profile, the IT Security Policy model permits the representation of modern access control models. The central concepts of this part are the system authorization and the role authorization. These two constructs are integrated, and the possibility is offered to express declarative restrictions on the subject and the resource of an authorization. Authorizations have a sign, positive or negative, and, in general, DAC, MAC, RBAC, and ABAC models can be represented. The expressivity of the authorization model is loosely comparable to what can be achieved with XACML, even if the different assumptions about the structure of subjects and resources do not permit establishing a formal containment relationship between the models.

Once the IT policy has been defined, reasoning services are offered to verify whether the policy satisfies a number of consistency constraints. The checks that are supported focus on identification of modality conflicts, redundant authorizations, and violations of Separation-of-Duty (SoD) constraints. Modality conflicts arise when rules with conflicting signs apply to the same access request and a

12. An event bus is a middleware component supporting the publish/subscribe communication model, where software components do not directly interact with each other, but communicate through events or messages mediated by the event bus. Events are produced (published) by a source component and consumed by one or multiple target components.

specified conflict resolution policy is not able to establish which of the rules has to be applied. The detection requires expanding all the subject and resource hierarchies that are used in the design of the IT Policy. Redundant authorizations are detected by looking for authorization rules that are dominated by other rules. These redundant rules can be omitted from the IT policy without changing system behavior. SoD constraints are specified using negative role authorizations, and violations are detected by identifying subjects that are able to acquire two roles denoted as conflicting. All the checks are implemented thanks to the use of Semantic Web tools, translating the IT policy into an OWL representation and then invoking adequate reasoning services. The outcome of this phase is a harmonized IT policy that is passed to the next phase.

Policy Refinement and Optimization

The harmonized IT Security Policy is the input, together with the landscape to configure, to the refinement phase that produces abstract configurations for the security controls available in the landscape. The Policy Refinement and Optimization application is a modular framework that drives the administrator in all the refinement phases and allows him or her to make informed decisions and to provide missing information. In fact, the Policy Refinement and Optimization application allows the selection of different refinement strategies (prefer the enforcement of security at the application layer, or message protection over channel protection, use infrastructure rather than the endpoint controls), or a manual selection of the devices to configure for each IT Security Policy.

The refinement is performed in two phases: the ontology-based refinement and the landscape configuration. During the ontology refinement, the IT Security Policy is enriched according to the landscape information using specialized ontologies that characterize the meaning of security concepts for each policy type (AC vs. DP) and for each device type (databases vs. operating systems). Moreover, the generated configurations are further adapted for the control that will actually enforce it (Windows vs. Linux AC policies) in order to simplify the transformation from abstract to concrete configurations. Additionally, the ontology also permits the automatic reasoning on the target landscape (to classify element according to the security level), to capture the complex dependencies among all the entities involved in policy enforcement and identify possible issues. Depending on the IT Security Policy to refine and the chosen strategy, the available controls are proposed for configuration according to their policy expressiveness and enforcement granularity, management costs, and the like, but the selection of the controls to actually configure is manually done by the administrators who have full control of AC policy enforcement. At the end of the ontology refinement, the configurations for access control endpoint security controls are generated (operating systems, databases, Web service containers). Additionally, for the IT Security Policies that require a further refinement (to configure the firewalls to allow users to reach the services they are authorized to use), for the ones that administrators decided to enforce using infrastructure elements (using VPN gateways to protect the communications between two networks), or for the ones that are not enforceable with endpoint security, the ontology refinement outputs the Logical Associations that are the input for the landscape configuration phase.

The landscape configuration takes into account all the information about the target landscape, including all the infrastructure controls and the entire network topology. Since at this level many different alternatives are usually available (different available controls, different configuration modes, different paths, etc.), the selection of the controls to configure and the rules to configure them are decided through an optimization process that decides not only based on single-control configuration, but also at the global landscape level. Many target functions can be selected by the administrator to maximize the overall performance, to minimize the risk exposure, and other balanced combinations. Additionally, the entire process can be customized with additional constraints; for instance, it is possible to implement the defense in depth, to configure at least two redundant controls. For example, the best-practice for firewall configuration imposed to block prohibited traffic as soon as possible may force the use of the border firewall to implement most of the IT policy. According to security and performance considerations, the Policy Refinement and Optimization application can move some of the rules from the border firewall to the periphery to avoid performance degradation. Another example concerns channel protection controls, where it is possible to avoid redundant channels or to aggregate end-to-end connections into basic VPNs according to the trustworthiness of the involved networks to improve performance. At the end of these phases, all the missing abstract configurations are generated. The set of abstract configurations is provided to Configuration Management Systems, which are expected first to transform them into the representation required by the respective system element and then to deploy this concrete configuration as to enforce the policy.

Configuration Validation and Audit

The deployment of concrete configuration marks the end of the implementation phase of the security life cycle. The PoSecCo application *Configuration Validation and Audit* then checks the presence of a concrete configuration in order to validate the *operation effectiveness* of implemented

security controls. This is achieved by using and extending the Security Content Automation Protocol (SCAP), a collection of standards developed by the NIST in order to foster the standardized representation, exchange, and automated processing of security knowledge. OVAL (Open Vulnerability Assessment Language), in particular, is used to check whether or not the PoSecCo-generated configuration is in place. Configuration discrepancies will be reflected by policy state changes on upper abstraction levels. The PCI DSS requirement to protect cardholder data, for instance, linked to the concrete configuration of a server's SSL feature, will enter the state *UNDER ANALYSIS* during the assessment of a configuration discrepancy, and *NOT FULFILLED* in case the assessment concludes that the discrepancy impacts security up to a point that the originating requirement is not fulfilled any longer (in case MD5 instead of SHA1 is used as a hash algorithm). In that context, OVAL has been extended to support the checking of application-level configurations in distributed environments, and to abstract check specifications from the way configuration is actually collected [54].

Operation effectiveness is one element of common IT audits, but alone is not sufficient to check whether a control framework put in place by an organization does address all security objectives and requirements. It is complemented by a check of the framework's *design effectiveness* in order to see whether planned controls are, in principle, suitable to reach the desired objectives (independent from the question of whether they have been implemented and properly configured). PoSecCo will support auditors and other stakeholders in this activity by allowing them to explore a subset of the models stored in MoVE and to formulate (OCL) queries. The subset defined depends on the actual audit scope, for example, a given business service and all connected elements. As an example, an auditor could query the model to check whether cardholder data is transmitted over communication links without a corresponding data protection policy. Finally, the model will also be used to generate draft audit programs that refer to OVAL checks for concrete configuration; these programs can be further enriched by auditors prior to the automated execution in the auditee's system. Here, the aim is to overcome today's audit practice of taking samples, but to enable complete and automated validation of all relevant configurations.

7. SUMMARY

This chapter briefly sketched different aspects of policy-based system management. It outlines achievements made since the late 1980s, when policies were first considered for system management purposes concerningareas such as policy information models, specification languages, or policy refinement and conflict detection. Some of this work culminated in international standards that foster a broader adoption of PBM. IBM succeeded in establishing the vision of autonomic computing, which forecasts the long-term development of future IT systems founded on mature and broadly applied policy technologies and techniques. This vision drives technology researchers from academia and industry, but it also serves as a vehicle to discuss non-technical matters related to autonomous and self-managing IT systems (ethical and socioeconomic questions).

Today, we observe that policy concepts are increasingly adopted by commercial products used in real-life systems. It comes without surprise that this application started by looking into single domains (network management), specification of access control policies, or system management. This restricted focus facilitates the implementation, and already suffices to realize economic benefits and service quality improvements. As yet, however, there exists no implementation of a PBM system that takes a holistic view of the many different kinds of policies at their various abstraction levels, and that considers the interdependencies of security mechanisms at various architecture layers. Moreover, today's application of PBM targets primarily the management of administrative domains belonging to one organizational entity, while new technologies and business models, such as virtualization and cloud services, result in the collaboration of many organizations across all layers of the application stack.

As such, at least two major technical challenges need to be addressed in order to move toward autonomous systems: (1) the detection of policy conflicts across architectural layers (cf. Chapter 45) and (2) the policy-based negotiation and collaboration of system elements that belong to different organizational entities (business partners). Efforts in the latter direction comprise, for instance, work on the high-level description of nonfunctional service properties and requirements, including security, which represents the basis for discovery and negotiation capabilities. This topic also stretches across compositional security, which investigates the preservation of security properties when systems are constructed from smaller components (with given properties).

We believe that the further development and increased adoption of policy technology by the IT industry strongly depends on the use of common specification languages, protocols, and architectures. While typical problems related to standardization also apply to the area of PBM (the fact that long-running standardization processes are sometimes outpaced by technological developments or undermined by strong market participants who seek to establish proprietary technology), we observe that past standardization efforts related to policies prove to be very successful. The DMTF standards CIM and WBEM are broadly supported by state-of-the-art tools for system management.

Finally, let's move on to the real interactive part of this chapter: review questions/exercises, hands-on projects, case projects, and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Policy-driven system management or policy-based management (PBM) is a research domain that aims at automatizing the management of small-scale computing systems.
2. True or False? IT systems are untraditionally structured according to several architecture layers, each layer offering a number of security capabilities that can support organizations in reaching desired security objectives.
3. True or False? Security management as performed today involves a variety of stakeholders with different job functions, expertise, and objectives, and using different tools and terminology.
4. True or False? Generally speaking, a policy is a definite goal, course or method of action to guide and determine present and future decisions.
5. True or False? The approach of PBM naturally leads to a so-called policy continuum, a hierarchy of policies that are subject to the same abstraction levels.

Multiple Choice

1. What makes it impractical to specify policies for individual system elements?
   A. Smaller systems
   B. Larger systems
   C. Management systems
   D. Network systems
   E. All of the above
2. What increases the correctness and consistency of configuration information, speeds up deployment processes, and supporst a variety of other security-related activities such as IT audits?
   A. Smaller systems
   B. Larger systems
   C. Configuration management systems
   D. Network systems
   E. All of the above
3. What requires a set of common functionalities related to the creation, storage, distribution, and enforcement of policies?
   A. Smaller systems
   B. Larger systems
   C. Policy-based systems
   D. Configuration management systems
   E. Network systems
4. What term has been coined by IBM to denote computing systems that manage themselves?
   A. Autonomic computin
   B. Self-protection
   C. Self-healing
   D. Autonomic elements
   E. All of the above
5. An important aspect in the design and implementation of a secure information system is the correct consideration of:
   A. remote control software
   B. email
   C. USB storage
   D. security principles
   E. risk analysis

1. INFORMATION SECURITY MANAGEMENT STANDARDS

A range of standards are specified by various industry bodies. Although specific to an industry, these standards can be used by any organization and adapted to its goals. Here we discuss the main organizations that set standards related to information security management.

Federal Information Security Management Act

At the U.S. federal level, the National Institute of Standards and Technology (NIST) has specified guidelines for implementing the Federal Information Security Management Act (FISMA). This act aims to provide the following standards shown in Figure 24.1.

The "Federal Information Security Management Framework Recommended by NIST"[2] sidebar describes the risk management framework as specified in FISMA. The activities specified in this framework are paramount in implementing an IT security management plan. Although specified for the federal government, this framework can be used as a guideline by any organization.

International Standards Organization

Another influential international body, the International Standards Organization and the International Electro Technical Commission, published ISO/IEC 17799:2005.[3]

• Standards for categorizing information and information systems by mission impact
• Standards for minimum security requirements for information and information systems
• Guidance for selecting appropriate security controls for information systems
• Guidance for assessing security controls in information systems and determining security control effectiveness
• Guidance for certifying and accrediting information systems

FIGURE 24.1 Specifications in the Federal Information Security Management Act.[1]

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00024-6

Federal Information Security Management Framework Recommended by NIST

Step 1: Categorize
In this step, information systems and internal information should be categorized based on impact.

Step 2: Select
Use the categorization in the first step to select an initial set of security controls for the information system and apply tailoring guidance as appropriate, to obtain a starting point for required controls.

Step 3: Supplement
Assess the risk and local conditions, including the security requirements, specific threat information, and cost/benefit analyses or special circumstances. Supplement the initial set of security controls with the supplement analyses.

Step 4: Document
The original set of security controls and the supplements should be documented.

Step 5: Implement
The security controls you identified and supplemented should be implemented in the organization's information systems.

Step 6: Assess
The security controls should be assessed to determine whether the controls are implemented correctly, are operating as intended, and are producing the desired outcome with respect to meeting the security requirements for the system.

Step 7: Authorize
Upon a determination of the risk to organizational operations, organizational assets, or individuals resulting from their operation, authorize the information systems.

Step 8: Monitor
Monitor and assess selected security controls in the information system on a continuous basis, including documenting changes to the system.

These standards establish guidelines and general principles for initiating, implementing, maintaining, and improving information security management in an organization. The objectives outlined provide general guidance on the commonly accepted goals of information security management. The standards consist of best practices of control objectives and controls in the areas of information security management shown in Figure 24.2.

These objectives and controls are intended to be implemented to meet the requirements identified by a risk assessment.

2. OTHER ORGANIZATIONS INVOLVED IN STANDARDS

Other organizations that are involved in information security management include The Internet Society[4] and the Information Security Forum.[5] These are professional societies with members in the thousands. The Internet Society is the organization home for the groups responsible for Internet infrastructure standards, including the Internet Engineering Task Force (IETF) and the Internet Architecture Board (IAB). The Information Security Forum is a global nonprofit organization of several hundred leading organizations in financial services, manufacturing, telecommunications, consumer goods, government, and other areas. It provides research into best practices and advice, summarized in its biannual Standard of Good Practice, which incorporates detailed specifications across many areas.

3. INFORMATION TECHNOLOGY SECURITY ASPECTS

The various aspects to IT security in an organization that must be considered include:

- Security policies and procedures
- Security organization structure
- IT security processes
  - Processes for a business continuity strategy
  - Processes for IT security governance planning
- Rules and regulations

Security Policies and Procedures

Security policies and procedures constitute the main part of any organization's security. These steps are essential for implementing IT security management: authorizing security roles and responsibilities to various security personnel; setting rules for expected behavior from users and security role players; setting rules for business continuity plans; and more. The security policy should be generally agreed to by most personnel in the organization and should have the support of the highest-level management. This helps in prioritization at the overall organization level.

The following list, illustrated in Figure 24.3, is a sample of some of the issues an organization is expected to

address in its policies.[6] Note, however, that the universal list is virtually endless, and each organization's list will consist of issues based on several factors, including its size and the value and sensitivity of the information it owns or deals with. Some important issues included in most security policies are:

- *Access control standards.* These are standards on controlling the access to various systems. These include password change standards.
- *Accountability.* Every user should be responsible for her own accounts. This implies that any activity under a particular user ID should be the responsibility of the user whose ID it is.
- *Audit trails.* There should be an audit trail recorded of all the activities under a user ID. For example, all the login, log-out activities for 30 days should be recorded. Additionally, all unauthorized attempts to access, read, write, and delete data and execute programs should be logged.

6. "Information technology | Security techniques | Code of practice for information security management, ISO/IEC 17799," The International Standards Organization and The International Electro Technical Commission, www.iso.org/iso (downloaded 10/20/2008).

7. "Information technology | Security techniques | Code of practice for information security management, ISO/IEC 17799," The International Standards Organization and The International Electro Technical Commission, www.iso.org/iso (downloaded 10/20/2008).

- *Backups.* There should be a clearly defined backup policy. Any backups should be kept in a secure area. A clear policy on the frequency of the backups and their recovery should be communicated to the appropriate personnel.
- *Disposal of media.* A clear policy should be defined regarding the disposal of media. This includes a policy on which hardware and storage media, such as disk drives, diskettes, and CD-ROMs, are to be destroyed. The level and method of destruction of business-critical information that is no longer needed should be well defined and documented. Personnel should be trained regularly on the principles to follow.
- *Disposal of printed matter.* Guidelines as to the disposal of printed matter should be specified and implemented throughout the organization. In particular, business-critical materials should be disposed properly and securely.
- *Information ownership.* All the data and information available in the organization should have an assigned owner. The owner should be responsible for deciding on access rights to the information for various personnel.
- *Managers' responsibility.* Managers at all levels should ensure that their staff understands the security policy and adheres to it continuously. They should be held responsible for recording any deviations from the core policy.
- *Equipment.* An organization should have specific guidelines about modems, portable storage, and other devices. These devices should be kept in a secured physical environment.
- *Communication.* Well-defined policy guidelines are needed for communication using corporate information systems. These include communications via emails, instant messaging, and so on.
- *Work procedures and processes.* Employees of an organization should be trained to secure their workstations when not in use. The policy can impose a procedure of logging off before leaving a workstation. It can also include quarantining any device (such as a laptop) brought from outside the organization before plugging it into the network.

Security Organization Structure

Various security-related roles need to be maintained and well defined. These roles and their brief descriptions are described here.[8]

End User

End users have a responsibility to protect information assets on a daily basis through adherence to the security policies that have been set and communicated. End-user compliance with security policies is key to maintaining information security in an organization because this group represents the most consistent users of the organization's information.

Executive Management

Top management plays an important role in protecting the information assets in an organization. Executive management can support the goal of IT security by conveying the extent to which management supports security goals and priorities. Members of the management team should be aware of the risks that they are accepting for the organization through their decisions or failure to make decisions. There are various specific areas on which senior management should focus, but some that are specifically appropriate are user training, inculcating and encouraging a security culture, and identifying the correct policies for IT security governance.

Security Officer

The security officer "directs, coordinates, plans, and organizes information security activities throughout the organization."[9]

Data/Information Owners

Every organization should have clearly identified data and information owners. These executives or managers should review the classification and access security policies and procedures. They should also be responsible for periodic audit of the information and data and its continuous security. They may appoint a data custodian in case the work required to secure the information and data is extensive and needs more than one person to complete.

Information System Auditor

Information system auditors are responsible for ensuring that the information security policies and procedures have been adhered to. They are also responsible for establishing the baseline, architecture, management direction, and compliance on a continuous basis. They are an essential part of unbiased information about the state of information security in the organization.

Information Technology Personnel

IT personnel are responsible for building IT security controls into the design and implementations of the systems. They are also responsible for testing these controls

An Agenda for Action for the Contingency Planning Process

The Disaster Recovery Institute International (DRII) associates eight tasks with the contingency planning process.[10] These are as follows (check all tasks completed):

_____**1.** Business impact analysis, to analyze the impact of outage on critical business function operations.

_____**2.** Risk assessment, to assess the risks to the current infrastructure and the incorporation of safeguards to reduce the likelihood and impact of disasters

_____**3.** Recovery strategy identification, to develop a variety of disaster scenarios and identify recovery strategies.

_____**4.** Recovery strategy selection, to select the appropriate recovery strategies based on the perceived threats and the time needed to recover.

_____**5.** Contingency plan development, to document the processes, equipment, and facilities required to restore the IT assets.

_____**6.** User training, to develop training programs to enable all affected users to perform their tasks.

_____**7.** Plan verification, for accuracy and adequacy.

_____**8.** Plan maintenance, for continuous upkeep of the plan as needs change.

periodically or whenever there is a change. They work with the executives and other managers to ensure compliance in all the systems under their responsibility.

Systems Administrator

A systems administrator is responsible for configuring the hardware and the operating system to ensure that the information systems and their contents are available for business as and when needed. These adminstrators are placed ideally in an organization to ensure security of these assets. They play a key role because they own access to the most vulnerable information assets of an organization.

IT Security Processes

To achieve effective IT security requires processes related to security management. These processes include business continuity strategy, processes related to IT security governance planning, and IT security management implementation.

Processes for a Business Continuity Strategy

As is the case with any strategy, the business continuity strategy depends on a commitment from senior management. This can include some of the analysis that is obtained by business impact assessment/risk analysis focused on business value drivers (see checklist: "An Agenda For Action For The Contingency Planning Process"). These business value drivers are determined by the main stakeholders from the organizations. Examples of these value drivers are customer service and intellectual property protection.[11]

Processes for IT Security Governance Planning

IT security governance planning includes prioritization as its major function. This helps in utilizing the limited sources of the organization. Determining priorities among the potential conflicting interests is the main focus of these processes. This includes budget setting, resource allocation, and, most important, the political process needed to prioritize in an organization.

Rules and Regulations

An organization is influenced by rules and regulations that influence its business. In a business environment marked by globalization, organizations have to be aware of both national and international rules and regulations. From an information security management perspective, various rules and regulations must be considered. These are listed in Figure 24.4. We give more details on some rules and regulations here:

- The Health Insurance Portability and Accountability Act (HIPAA) requires the adoption of national standards for electronic healthcare transactions and national identifiers for providers, health insurance plans, and employers. Healthcare providers have to protect the personal medical information of the customer to comply with this law. Similarly, the Gramm-Leach-Bliley Act of 1999 (GLBA), also known as the Financial Services Modernization Act of 1999, requires financial companies to protect the information about individuals that it collects during transactions.
- The Sarbanes-Oxley Act of 2002 (SOX). This law requires companies to protect and audit their financial data. The chief information officer and other senior executives are held responsible for reporting and

USA PATRIOT Act

FIGURE 24.4 Rules and regulations related to information security management.

auditing an organization's financial information to regulatory and other agencies.

- State Security Breach Notification Laws (California and many others) require businesses, nonprofits, and state institutions to notify consumers when unencrypted "personal information" might have been compromised, lost, or stolen.
- The Personal Information Protection and Electronics Document Act (PIPEDA) supports and promotes electronic commerce by protecting personal information that is collected, used, or disclosed in certain circumstances, by providing for the use of electronic means to communicate or record information or transactions, and by amending the Canada Evidence Act, the Statutory Instruments Act, and the Statute Revision Act that is in fact the case.
- The Computer Fraud and Abuse Act, or CFAA (also known as Fraud and Related Activity in Connection with Computers), is a U.S. law passed in 1986 and intended to reduce computer crimes. It was amended in 1994, 1996, and 2001 by the U.S.A. PATRIOT Act.[12]

The following sidebar, "Computer Fraud and Abuse Act Criminal Offences," lists criminal offences covered under this law.[13]

The U.S.A. PATRIOT Act of 2001 increased the scope and penalties of this act by:

- Raising the maximum penalty for violations to ten years (from five) for a first offense and 20 years (from ten) for a second offense
- Ensuring that violators only need to intend to cause damage generally, not intend to cause damage or other specified harm over the $5000 statutory damage threshold
- Allowing aggregation of damages to different computers over a year to reach the $5000 threshold
- Enhancing punishment for violations involving any (not just $5000 in) damage to a government computer involved in criminal justice or the military
- Including damage to foreign computers involved in U. S. interstate commerce
- Including state law offenses as priors for sentencing;
- Expanding the definition of loss to expressly include time spent investigating
- Responding (this is why it is important for damage assessment and restoration)

These details are summarized in Figure 24.5.

The PATRIOT Act of 2001 came under criticism for a number of reasons. There are fears that the Act is an invasion of privacy and infringement on freedom of speech. Critics also feel that the Act unfairly expands the powers of the executive branch and strips away many crucial checks and balances.

The original act has a sunset clause that would have caused many of the law's provisions to expire in 2005. The Act was reauthorized in early 2006 with some new safeguards and with expiration dates for its two most controversial powers, which authorize roving wiretaps and secret searches of records.

4. SUMMARY

Information technology security management consists of processes to enable organizational structure and technology to protect an organization's IT operations and assets against internal and external threats, intentional or otherwise. These processes are developed to ensure confidentiality, integrity, and availability of IT systems. There are various aspects to the IT security in an organization that need to be considered. These include security policies and procedures, security organization structure, IT security processes, and rules and regulations.

Computer Fraud and Abuse Act Criminal Offences

(a) Whoever —
(1) having knowingly accessed a computer without authorization or exceeding authorized access, and by means of such conduct having obtained information that has been determined by the United States Government pursuant to an Executive order or statute to require protection against unauthorized disclosure for reasons of national defense or foreign relations, or any restricted data, as defined in paragraph y. of section 11 of the Atomic Energy Act of 1954, with reason to believe that such information so obtained could be used to the injury of the United States, or to the advantage of any foreign nation willfully communicates, delivers, transmits, or causes to be communicated, delivered, or transmitted, or attempts to communicate, deliver, transmit or cause to be communicated, delivered, or transmitted the same to any person not entitled to receive it, or willfully retains the same and fails to deliver it to the officer or employee of the United States entitled to receive it;
(2) intentionally accesses a computer without authorization or exceeds authorized access, and thereby obtains —
(A) information contained in a financial record of a financial institution, or of a card issuer as defined in section 1602 (n) of title 15, or contained in a file of a consumer reporting agency on a consumer, as such terms are defined in the Fair Credit Reporting Act (15 U.S.C. 1681 et seq.);
(B) information from any department or agency of the United States; or
(C) information from any protected computer if the conduct involved an interstate or foreign communication;
(3) intentionally, without authorization to access any nonpublic computer of a department or agency of the United States, accesses such a computer of that department or agency that is exclusively for the use of the Government of the United States or, in the case of a computer not exclusively for such use, is used by or for the Government of the United States and such conduct affects that use by or for the Government of the United States;
(4) knowingly and with intent to defraud, accesses a protected computer without authorization, or exceeds authorized access, and by means of such conduct furthers the intended fraud and obtains anything of value, unless the object of the fraud and the thing obtained consists only of the use of the computer and the value of such use is not more than $5,000 in any 1-year period;
(5)
(A)
(i) knowingly causes the transmission of a program, information, code, or command, and as a result of such conduct, intentionally causes damage without authorization, to a protected computer;
(ii) intentionally accesses a protected computer without authorization, and as a result of such conduct, recklessly causes damage; or
(iii) intentionally accesses a protected computer without authorization, and as a result of such conduct, causes damage; and
(B) by conduct described in clause (i), (ii), or (iii) of subparagraph (A), caused (or, in the case of an attempted offense, would, if completed, have caused) –
(i) loss to 1 or more persons during any 1-year period (and, for purposes of an investigation, prosecution, or other proceeding brought by the United States only, loss resulting from a related course of conduct affecting 1 or more other protected computers) aggregating at least $5,000 in value;
(ii) the modification or impairment, or potential modification or impairment, of the medical examination, diagnosis, treatment, or care of 1 or more individuals;
(iii) physical injury to any person;
(iv) a threat to public health or safety; or

(v) damage affecting a computer system used by or for a government entity in furtherance of the administration of justice, national defense, or national security;
(6) knowingly and with intent to defraud traffics (as defined in section 1029) in any password or similar information through which a computer may be accessed without authorization, if —
(A) such trafficking affects interstate or foreign commerce; or
(B) such computer is used by or for the Government of the United States;
(7) with intent to extort from any person any money or other thing of value, transmits in interstate or foreign commerce any communication containing any threat to cause damage to a protected computer; shall be punished as provided in subsection (c) of this section.
(b) Whoever attempts to commit an offense under subsection (a) of this section shall be punished as provided in subsection (c) of this section.
(c) The punishment for an offense under subsection (a) or (b) of this section is —
(1)
(A) a fine under this title or imprisonment for not more than ten years, or both, in the case of an offense under subsection (a)(1) of this section which does not occur after a conviction for another offense under this section, or an attempt to commit an offense punishable under this subparagraph; and
(B) a fine under this title or imprisonment for not more than twenty years, or both, in the case of an offense under subsection (a)(1) of this section which occurs after a conviction for another offense under this section, or an attempt to commit an offense punishable under this subparagraph;
(2)
(A) except as provided in subparagraph (B), a fine under this title or imprisonment for not more than one year, or both, in the case of an offense under subsection (a)(2), (a)(3), (a)(5)(A)(iii), or (a)(6) of this section which does not occur after a conviction for another offense under this section, or an attempt to commit an offense punishable under this subparagraph;
(B) a fine under this title or imprisonment for not more than 5 years, or both, in the case of an offense under subsection (a)(2), or an attempt to commit an offense punishable under this subparagraph, if —
(i) the offense was committed for purposes of commercial advantage or private financial gain;
(ii) the offense was committed in furtherance of any criminal or tortious act in violation of the Constitution or laws of the United States or of any State; or
(iii) the value of the information obtained exceeds $5,000; and
(C) a fine under this title or imprisonment for not more than ten years, or both, in the case of an offense under subsection (a)(2), (a)(3) or (a)(6) of this section which occurs after a conviction for another offense under this section, or an attempt to commit an offense punishable under this subparagraph;
(3)
(A) a fine under this title or imprisonment for not more than five years, or both, in the case of an offense under subsection (a)(4) or (a)(7) of this section which does not occur after a conviction for another offense under this section, or an attempt to commit an offense punishable under this subparagraph; and
(B) a fine under this title or imprisonment for not more than ten years, or both, in the case of an offense under subsection (a)(4), (a)(5)(A)(iii), or (a)(7) of this section which occurs after a conviction for another offense under this section, or an attempt to commit an offense punishable under this subparagraph;
(4)
(A) except as provided in paragraph (5), a fine under this title, imprisonment for not more than 10 years, or both, in the case of an offense under subsection (a)(5)(A)(i), or an attempt to commit an offense punishable under that subsection;
(B) a fine under this title, imprisonment for not more than 5 years, or both, in the case of an offense under subsection (a)(5)(A)(ii), or an attempt to commit an offense punishable under that subsection;
(C) except as provided in paragraph (5), a fine under this title, imprisonment for not more than 20 years, or both, in the case of an offense under subsection (a)(5)(A)(i) or (a)(5)(A)(ii), or an attempt to commit an offense punishable under either subsection, that occurs after a conviction for another offense under this section; and
(5)
(A) if the offender knowingly or recklessly causes or attempts to cause serious bodily injury from conduct in violation of subsection (a)(5)(A)(i), a fine under this title or imprisonment for not more than 20 years, or both; and
(B) if the offender knowingly or recklessly causes or attempts to cause death from conduct in violation of subsection (a)(5)(A)(i), a fine under this title or imprisonment for any term of years or for life, or both.
(d)
(1) The United States Secret Service shall, in addition to any other agency having such authority, have the authority to investigate offenses under this section.
(2) The Federal Bureau of Investigation shall have primary authority to investigate offenses under subsection (a)(1) for any cases involving espionage, foreign counterintelligence, information protected against unauthorized disclosure for reasons of national defense or foreign relations, or Restricted Data (as that term is defined in section 11y of the Atomic Energy Act of 1954 (42 U.S.C. 2014 (y)), except for offenses affecting the duties of the United States Secret Service pursuant to section 3056 (a) of this title.

(3) Such authority shall be exercised in accordance with an agreement which shall be entered into by the Secretary of the Treasury and the Attorney General.

(e) As used in this section –

(1) the term "computer" means an electronic, magnetic, optical, electrochemical, or other high speed data processing device performing logical, arithmetic, or storage functions, and includes any data storage facility or communications facility directly related to or operating in conjunction with such device, but such term does not include an automated typewriter or typesetter, a portable hand held calculator, or other similar device;

(2) the term "protected computer" means a computer –

(A) exclusively for the use of a financial institution or the United States Government, or, in the case of a computer not exclusively for such use, used by or for a financial institution or the United States Government and the conduct constituting the offense affects that use by or for the financial institution or the Government; or

(B) which is used in interstate or foreign commerce or communication, including a computer located outside the United States that is used in a manner that affects interstate or foreign commerce or communication of the United States;

(3) the term "State" includes the District of Columbia, the Commonwealth of Puerto Rico, and any other commonwealth, possession or territory of the United States;

(4) the term "financial institution" means –

(A) an institution, with deposits insured by the Federal Deposit Insurance Corporation;

(B) the Federal Reserve or a member of the Federal Reserve including any Federal Reserve Bank;

(C) a credit union with accounts insured by the National Credit Union Administration;

(D) a member of the Federal home loan bank system and any home loan bank;

(E) any institution of the Farm Credit System under the Farm Credit Act of 1971;

(F) a broker-dealer registered with the Securities and Exchange Commission pursuant to section 15 of the Securities Exchange Act of 1934;

(G) the Securities Investor Protection Corporation;

(H) a branch or agency of a foreign bank (as such terms are defined in paragraphs (1) and (3) of section 1(b) of the International Banking Act of 1978); and

(I) an organization operating under section 25 or section 25(a) [2] of the Federal Reserve Act;

(5) the term "financial record" means information derived from any record held by a financial institution pertaining to a customer's relationship with the financial institution;

(6) the term "exceeds authorized access" means to access a computer with authorization and to use such access to obtain or alter information in the computer that the accesser is not entitled so to obtain or alter;

(7) the term "department of the United States" means the legislative or judicial branch of the Government or one of the executive departments enumerated in section 101 of title 5;

(8) the term "damage" means any impairment to the integrity or availability of data, a program, a system, or information;

(9) the term "government entity" includes the Government of the United States, any State or political subdivision of the United States, any foreign country, and any state, province, municipality, or other political subdivision of a foreign country;

(10) the term "conviction" shall include a conviction under the law of any State for a crime punishable by imprisonment for more than 1 year, an element of which is unauthorized access, or exceeding authorized access, to a computer;

(11) the term "loss" means any reasonable cost to any victim, including the cost of responding to an offense, conducting a damage assessment, and restoring the data, program, system, or information to its condition prior to the offense, and any revenue lost, cost incurred, or other consequential damages incurred because of interruption of service; and

(12) the term "person" means any individual, firm, corporation, educational institution, financial institution, governmental entity, or legal or other entity.

(f) This section does not prohibit any lawfully authorized investigative, protective, or intelligence activity of a law enforcement agency of the United States, a State, or a political subdivision of a State, or of an intelligence agency of the United States.

(g) Any person who suffers damage or loss by reason of a violation of this section may maintain a civil action against the violator to obtain compensatory damages and injunctive relief or other equitable relief. A civil action for a violation of this section may be brought only if the conduct involves 1 of the factors set forth in clause (i), (ii), (iii), (iv), or (v) of subsection (a)(5)(B). Damages for a violation involving only conduct described in subsection (a)(5)(B)(i) are limited to economic damages. No action may be brought under this subsection unless such action is begun within 2 years of the date of the act complained of or the date of the discovery of the damage. No action may be brought under this subsection for the negligent design or manufacture of computer hardware, computer software, or firmware.

(h) The Attorney General and the Secretary of the Treasury shall report to the Congress annually, during the first 3 years following the date of the enactment of this subsection, concerning investigations and prosecutions under subsection (a)(5).

Security policies and procedures are essential for implementing IT security management: authorizing security roles and responsibilities to various security personnel; setting rules for expected behavior from users and security role players; setting rules for business continuity plans; and more. The security policy should be generally agreed to by most personnel in the organization and have support from high-level management. This helps in prioritization at the overall organization level. The IT security processes are essentially part of an organization's risk management processes and business continuity strategies. In a business environment marked by globalization, organizations have to be aware of both national and international rules and regulations. Their information security and privacy policies must conform to these rules and regulations.

Finally, let's move on to the real interactive part of this Chapter: review questions/exercises, hands-on projects, case projects and optional team case project. The answers and/or solutions by chapter can be found in the Online Instructor's Solutions Manual.

CHAPTER REVIEW QUESTIONS/EXERCISES

True/False

1. True or False? Security policies and procedures do not constitute the main part of any organization's security.
2. True or False? Various security-related roles do not need to be maintained and well defined.
3. True or False? End users have a responsibility to protect information assets on a daily basis through adherence to the security policies that have been set and communicated.
4. True or False? Top management does not play an important role in protecting the information assets in an organization.
5. True or False? The security officer "directs, coordinates, plans, and organizes information security activities throughout the organization.

Multiple Choice

1. Who are responsible for ensuring that the information security policies and procedures have been adhered to?
   A. Information owners
   B. Information system auditors
   C. Security officers
   D. Executive management
   E. All of the above
2. Who is responsible for building IT security controls into the design and implementations of the systems?
   A. Information owners
   B. Information system auditors
   C. IT personnel
   D. Systems Administrator
   E. All of the above
3. Who is responsible for configuring the hardware and the operating system to ensure that the information systems and their contents are available for business as and when needed?
   A. Information System Auditor
   B. Information Owners
   C. Systems Administrator
   D. Security Officer
   E. Executive Management
4. What analyzes the impact of outage on critical business function operations?
   A. Risk assessment
   B. Recovery strategy identification
   C. Recovery strategy selection
   D. Business impact analysis
   E. All of the above
5. What documents the processes, equipment, and facilities required to restore the IT assets?
   A. Contingency plan development
   B. User training
   C. Plan verification
   D. Plan maintenance
   E. Recovery strategy selection

EXERCISE

Problem

Why does an organization need a Business Continuity Plan (BCP)?

Hands-On Projects

Project

How often should the BCP / DR (Disaster Recovery) plans be reviewed?

Case Projects

Problem

What are some guidelines for identifying mission critical functions?

Optional Team Case Project

Problem

Why should an organization certify their IT security management system?

Chapter 25

Online Identity and User Management Services

Tewfiq El Maliki
University of Applied Sciences of Geneva, tewfiq.elmaliki@hesge.ch

Jean-Marc Seigneur
University of Geneva, jean-marc.seigneur@reputaction.com

1. INTRODUCTION

Anytime, anywhere mobile computing is becoming easier, more attractive and even cost-effective: the mobile devices carried by the roaming users offer more and more computing power and functionalities including sensing and providing location-awareness [1]. A lot of computing devices are also deployed in the environments where the users evolve; for example, intelligent home appliances or RFID-enabled fabrics. In this ambient intelligent world, the choices of identity mechanisms will have a large impact on social, cultural, business and political aspects. Moreover, Internet of things will generate more complicated privacy problems [2]. Identity has become a burden on the online world. When it is stolen it engenders a massive fraud, principally in online services which generate a lack of confidence in doing business for providers and frustration for users.

Therefore, the whole of society would suffer from the demise of privacy which is a real human need. As people have hectic live and cannot spend their time administering their digital identities, we need consistent identity management platforms and technologies enabling usability and scalability among others [3]. In this paper, we survey how the requirements have evolved for mobile user-centric identity management and their associated technologies.

The chapter is organized as follows. First, we present the evolution of identity management requirements. Section 4 surveys how the different most advanced identity management technologies fulfill present day requirements. Section 5 covers "social login" that is the major identity management technical solution that has emerged after writing the first version of this book chapter and that has nowadays gained a stronger user adoption than the other solutions surveyed in Section 4 although a few of them are used underneath "social login". Section 6 discusses how mobility can be achieved in the field of identity management in an ambient intelligent/ubiquitous computing world.

2. EVOLUTION OF IDENTITY MANAGEMENT REQUIREMENTS

In this section, we first define what we mean by a digital identity. Later in the chapter, we summarize all the different requirements and detail the most important ones in the following subsections, namely, privacy, usability and mobility.

Digital Identity Definition

A digital identity is a representation of an entity in a specific context [4]. For a long time, a digital identity was considered as the equivalent of our real life identity which indicates some of our attributes:

- Who we are, Name, Citizenship, Birthday;
- What we like, our favorite Reading, Food, Clothes, etc;
- What our reputation is, whether we are honest, without any problems, etc.

A digital identity was seen as an extended identity card or passport containing almost the same information. However, recent work [5] has argued that the link between the real-world identity and a digital identity is not always mandatory. For example, on e-Bay what matters is to know whether the seller's digital identity reputation has been remarkable and that the seller can prove that she controls that digital identity. It is less important to know that her real-world national identity is from the Bermuda Islands, where suing anybody is rather unlikely

Computer and Information Security Handbook. DOI: http://dx.doi.org/10.1016/B978-0-12-394397-2.00025-8

to succeed. It should be underlined that in a major identity management initiative [6], a digital identity is defined as "the distinguishing character or personality of an individual. An identity consists of traits, attributes, and preferences upon which one may receive personalized services. Such services could exist online, on mobile devices at work, or in many other places", that is, without mentioning a mandatory link to the real-world identity behind the digital identity.

The combination of virtual world with ubiquitous connectivity has changed the physical constraints to entirely new set of requirements as the associated security issues such phishing, spam, and identity theft has emerged. They are aggravated by the mobility of the user, the temporary and anonymity of cyber relationships. We are going toward new truly virtual world with always the implication of human. Therefore, we are facing the problem of determining the identity of our interlocutor and the accuracy of his/her claims. Simply using strong authentication will not resolve all these security issues. Digital identity management is a key issue that will ensure not only the service and functionality expectations but also security and privacy.

Identity Management Overview

A model of identity can been as follows [7]:

- User who wants to access to a service
- Identity Provider (IdP): is the issuer of user identity
- Service Provider (SP): is the relay party imposing identity check
- Identity (Id): is a set user's attributes
- Personal Authentication Device (PDA): Device holding various identifiers and credentials and could be used for mobility

Figure 25.1 lists the main components of identity management. The relationship between entities, identities and identifiers are shown in Figure 25.2, which illustrates that an entity, such as a user, may have multiple identities, and each identity may consist of multiple attributes that can be unique or non-unique identifiers.

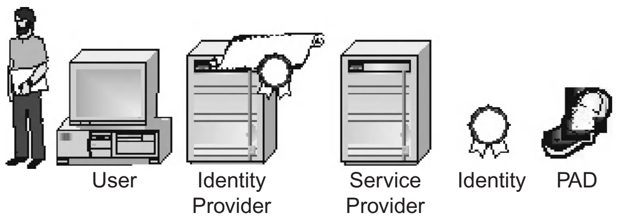

FIGURE 25.1 Identity management main components.

Identity management refers to "the process of representing, using, maintaining, deprovisioning and authenticating entities as digital identities in computer networks".

Authentication is the process of verifying claims about holding specific identities. A failure at this stage will threaten the validity in the entire system. The technology is constantly finding stronger authentication using claims based on:

- Something you know: password, PIN
- Something you have: one-time-password
- Something you are: your voice, face, fingerprint (Biometrics)
- Your position
- Some combination of the four.

The BT report [3] has highlighted some interesting points to meet the challenges of identity theft and fraud:

- Developing risk calculation and assessment methods
- Monitoring user behavior to calculate risk
- Building trust and value with the user or consumer
- Engaging the cooperation of the user or consumer with transparency and without complexity or shifting the liability to consumer
- Taking a staged approach to authentication deployment and process challenges, using more advanced technologies

Digital identity should mange three connected vertexes: usability, cost and risk as illustrated in Figure 25.3.

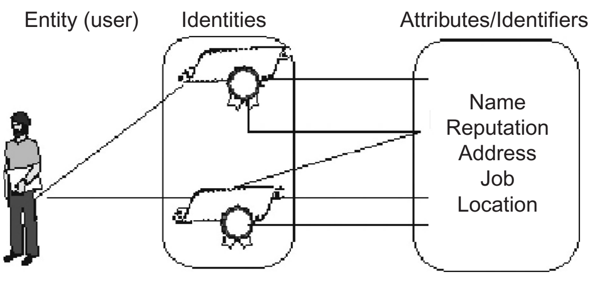

FIGURE 25.2 Relationship between identities, identifiers and entity.

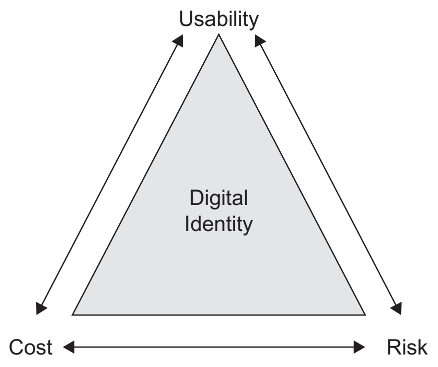

FIGURE 25.3 Digital identity environment to manage.

The user should be aware of the risk he/she facing if his/her device/software's security is compromised. The usability is the second aspect that should be guaranty to the user unless he/she will find the system difficult which could be a source of security problem. Indeed, a lot of users when they are flooded by passwords write them down and hide them in a secrete place under their keyboard. Furthermore, the difficulty to deploy and manage a large number of identities discourages the use of identity management system. The cost of a system should be well studied and balanced related to risk and usability. Many systems such as one-Time-Password token are not widely used because they are too costly for a widespread deployment for large institutions. Traditionally identity management was seen as service provider centric as it was designed to fulfill the requirements of service provider, such as cost effectiveness and scalability. The users were neglected in many aspects because they were forced to memorize difficult or too many passwords. Identity management systems are elaborated to deal with the following core facets [8]:

- Reducing identity theft: The problem of identity theft is becoming a major one, mainly in the online environment. The providers need more efficient system to tackle this problem.
- Management: The amount of digital identities per person will increase, so the users need convenient support to manage these identities and the corresponding authentication.
- Reachability: The management of reachability allows user to handle their contacts to prevent misuse of their address (spam) or unsolicited phone calls.
- Authenticity: Ensuring authenticity with authentication, integrity and non-repudiation mechanisms can prevent from identity theft.
- Anonymity and pseudonymity: providing anonymity prevent from tracking or identifying the users of a service.
- Organization personal data management: A quick method to create, modify a delete work accounts is needed, especially in big organizations.

Without improved usability of identity management [8], for example, weak passwords used by users on many Web sites, the number of successful attacks will remain high. To facilitate interacting with unknown entities, simple recognition rather than authentication of a real-world identity has been proposed, which usually involves manual enrollment steps in the real-world [5]. Usability is indeed enhanced, if there is no manual task needed. There might be a weaker level of security but that level may be sufficient for some actions, such as, logging to a mobile game platform. Single Sign-On (SSO) is the name given to the requirements of eliminating multiple password issues and dangerous password. When we use multiple user Id's and passwords just to use the emails systems and file servers at work, we feel the inconvenience that comes from having multiple identities. The second problem is the scattering of identity data which causes problems for the integration of IT systems. Moreover, it simplifies the end-user experience and enhances security via identity-based access technology.

Microsoft first largest identity management system was Passport Network. It was a very large and widespread Microsoft Internet service to be an identity provider for the MSN and Microsoft properties, and to be an identity provider for the Internet. However, with Passport, Microsoft was suspected by many persons of intending to have an absolute control over the identity information of Internet users and thus exploiting them for its own interests. Passport failed to become the Internet identity management tool. Since then, Microsoft has clearly understood that an identity management solution cannot succeed unless some basic rules are respected [9]. That's why Microsoft's Identity Architect, Kim Cameron, has stated the seven laws of identity. His motivation was purely practical in determining the prerequisites of successful identity management system. He formulated the essential principles to maintain privacy and security.

1. User control and consent over the handling of their data.
2. Minimal disclosure of data, and for specified purpose.
3. Information should only be disclosed to people who have a justifiable need for it.
4. The system must provide identifiers for both bilateral relationships between parties, and for incoming unsolicited communications.
5. It must support diverse operators and technologies.
6. It must be perceived as highly reliable and predictable.
7. There must be a consistent user experience across multiple identity systems and using multiple technologies.

Most systems do not fulfill several of these tests particularly they are deficient in fine-tuning the access control over identity to minimize disclosure of data. The formulated Cameron's principles are very clear but they are not enough explicit to compare finely identity management systems. That's why we will define explicitly the identity requirements.

Privacy Requirement

Privacy is a central issue, due to the fact that the official authorities of almost all countries have legal strict policies related to identity. It is often treated in the case of identity management because the management deals with personal information and data. Therefore, it is important

to give a definition. Alan F. Westin defines privacy as "*the claim of individuals, groups and institutions to determine for themselves, when, how and to what extent information about them is communicated to others*" [2]. However, we will use Cooley's broader definition of privacy [10]: "the right to be let alone", because it also emphasizes the problems related to disturbing the user's attention, for example, by email spam.

User Centricity

The evolution of the identity management system is toward the simplification of user experience and reinforcing authentication. It is well known that a poor usability implies the weakness of authentication. Mainly federated management has responded to some of these requirements by facilitating the use and the managing of identifiers and credentials in the boundary of a federated domain. Nevertheless, it is improbable that only one federated domain will subsist. Moreover, different levels of sensitivity and risks of different services will need different kinds of credentials. It is obvious that we should give users support and atomization of the identity management on the user's side.

A new paradigm must be introduced to solve the problems of usability, scalability and universal SSO. Therefore, a user-oriented paradigm has emerged which is called user-centric identity management. The word user controlled management [11] is the first used to explain user-centric management model. Recent federated identity management systems keep strong end-user controls over how identity information is disseminated amongst members of the federation. This new paradigm gives the user full control over his/her identity by notifying him the information collected and by guarantying his/her consent for any type of manipulation over collected information. A user control and consent is also defined as the first law in Cameron's Laws of Identity [9]. A user-centric identity management system supports the user's control and considers user-centric architecture and usability aspects. There is no uniform definition but "user-centric identity management is understood to mean digital identity infrastructure where an individual end-user has substantially independent control over the dissemination and use of their identifier(s) and personally-identifiable information (PII)."[12] See Figure 25.4. We can also give this definition of user centricity.

In user-centric identity management the user has the full control over hi/hers identity and consistent user experience during all transaction when accessing his/her services.

In other terms it means that it allows the user to keep at least some or total control over his/her personal data. One of the principles of user-centric identity is the idea that the user of a Web service should have full control over his/her identity information (see checklist: "An Agenda For Action For The User-Centric Identity Paradigm").

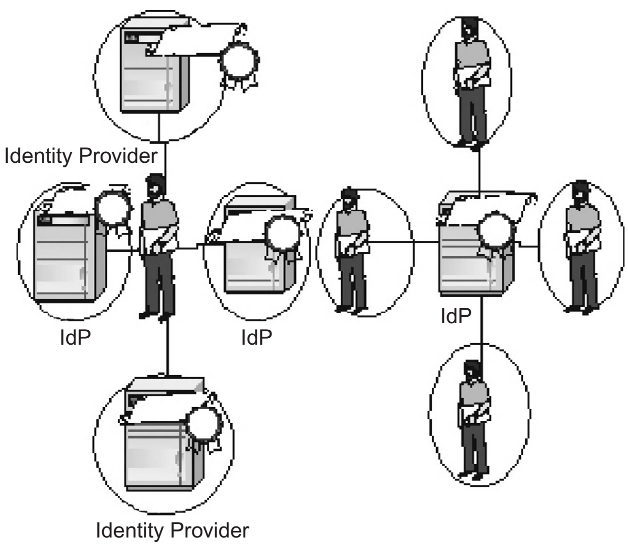

FIGURE 25.4 IdP centric and User-centric models.

An Agenda for Action for the User-Centric Identity Paradigm

A lot of technology discussion and solution has been focusing on service provider and rarely on user's perspectives. User-centric identity paradigm is a real evolution because it moves information technology architecture forward for the users with the following advantages. These are as follows (check all tasks completed):

_____**1** Empower the total control of users over their privacy.
_____**2** Usability, as users are using the same identity for each identity transaction.
_____**3** Give a consistent user's experience thanks to uniformity of identity interface.
_____**4** Limit identity attacks (Phishing).
_____**5** Limit reachability/disturbances, such as spam.
_____**6** Review policies on both sides when necessary, identity providers and service providers (Web sites).
_____**7** Huge scalability advantages as the Identity Provider does not have to get any prior knowledge about the Service Provider.
_____**8** Assure secure conditions when exchanging data.
_____**9** Decouple digital identity from applications.
_____**10** Pluralism of Operators and Technologies.

User-centricity approach allows the user to gain access anonymously as she detains the full control on his/her identity. Of course, full anonymity [26] and unlinkability may lead to increased misuse by anonymous users. Then, Pseudonymity is alternative which is more suitable to the e-commerce environment. In this regard, anonymity must be guaranty at the application and at network levels. Some frameworks have been proposed to ensure user-centric anonymity using the concepts of One-task Authorization key and Binding Signature [26].

Usability Requirement

The security is also compromised with the proliferation of the user's password and even by it's weakness. Indeed, some users note their passwords on scratch pads, because their memorization poses problem. The recent FFIEC guidance on authentication in online banking reports that "Account fraud and identity theft are frequently the result of single factor (Id/password) authentication exploitation" [14]. From then on, the security must be user oriented as he/her is the effective person concerned with it and a lot of recent attacks take advantage from the lack of awareness of users attacks (i.e. spoofing, pharming and phishing) [15]. Without strong control and improved usability [16] of identity management some attacks will be always possible. To facilitate interacting with unknown entities, simple recognition rather than authentication of a real-world identity, which usually involves manual enrollment steps in the real-world, has been proposed [5]. Usability is indeed enhanced if there is no manual task needed. There might be a weaker level of security reached but that level may be sufficient for some actions, such as, logging to a mobile game platform.

Single Sign-On (SSO) is the name given to the requirements of eliminating multiple password issues and dangerous password. When we use multiple user Id's and passwords just to use the emails systems and file servers at work, we feel the pain that comes from having multiple identities. The second problem is the scattering of identity data which causes problem for the integration of IT systems. Moreover, it simplifies the end-user experience and enhances security via identity-based access technology. Therefore, we offer these features:

- Flexible authentication
- Directory independence
- Session and password management
- Seamless

3. THE REQUIREMENTS FULFILLED BY IDENTITY MANAGEMENT TECHNOLOGIES

This section provides an overview of identity management solutions from identity 1.0 to identity 2.0 and how they address the requirements introduced in Section 2. We will focus on related standards XRI and LID issued from Yadis project and platforms mainly ID-WSF, OpenID, Higgins, InfoCard and Sxip. At the end, we treat the identity management in the field of mobility.

Evolution of Identity Management

This section provides an overview of almost all identity management 1.0 (See Figure 25.5). First of all, we describe the silo model, then different kind of centralized model and the federated identity management.

4. IDENTITY MANAGEMENT 1.0

In the real world I use my identity card to prove who I am. How about the online world?

The first digital identity appeared when the user was associated with the pair (username, password) or any other shared secret. This method is used for authentication when connecting to an account or a directory. It proves your identity if you follow the guidelines strictly otherwise there is no proof. In fact, it is a single authority using opaque trust decision without any credentials (cryptographic proofs) choice or portability.

In the context of Web access, the user must enroll for every non-related service, generally with different user interfaces and follows diverse policies and protocols. Thus, the user has a non-consistent experience and deals with different identity copies. In addition, some problems related to privacy have also emerged. Indeed, our privacy was potentially invaded by sites. It is clear that sites have a privacy policy, but there is no control from the user on his/her identity. What are the conditions for using these

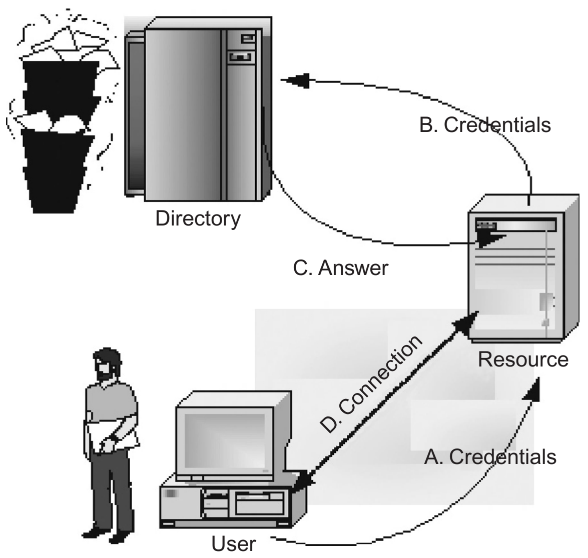

FIGURE 25.5 Identity 1.0 principle.

data? How can we improve our privacy? And to what granularity we allow them to use it?

The same problem is revealed when having access to resources. The more resources, the more management we have. It is an asymmetric trust. And, the policy decision maybe opaque.

It allows access with an opaque trust decision and a single centralized authority without a credentials choice. It is a silo model [17] because it is neither portable nor scalable. This is Identity 1.0.

The identity management appeared with these problems in the 1980s. The fist identity management system was the Rec. X.500, developed by ITU [1], covering directory services like Directory Access Protocol (DAP). ISO was also associated to the development of the standard. Like a lot of ITU standards, this one was very heavy and complex. A light version appeared in the 1990s for DAP. It was LDAP which was standardized by the IETF and widespread and adopted by Netscape. Microsoft has invented an equivalent Active Directory, and for users, they introduced Passport. It is also the ITU which standardized X.509 for identities related to certificates. It is the format currently recognized. It is a small file, generated by an authority of certification.

If there is a loss or a usurpation of the certificate, it can always be revoked by the authority of certification. This is for single user and what about business corporations who have automated their procedures and have a proliferation of applications with de-provisioning but still been in a domain-centric model. What about resources shared between domains?

Silo Model

The main identity management system deployed currently in the world of the Internet is known as the silo model, as shown in Figure 25.6. Indeed, the identity provider and service provider are mixed up and they share the same space. The identity management environment is put in place and operated by a single entity for a fixed users' community.

Users of different services must have different accounts and therefore reenter the same information about their identity which increases the difficulty of management. Moreover, the users are overloaded by identity and password to memorize which produces a significant barrier to usage.

A real problem is the forgetfulness of passwords due to the infrequent use of some of these data. This can obviously lead to a higher cost of service provisions. This is for single users, what about Enterprises that have automated their procedures and have a proliferation of applications with de-provisioning but are still in a domain-centric model? What about resources shared between domains?

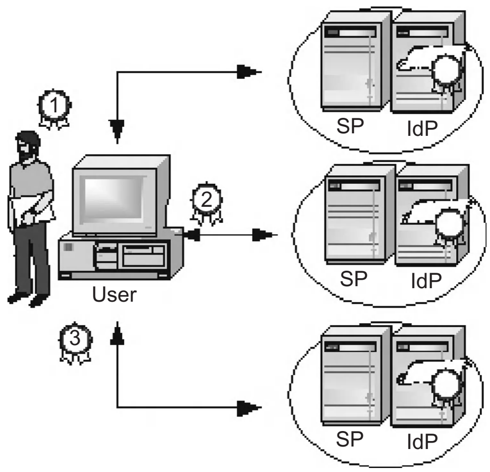

FIGURE 25.6 Identity silo model.

Silo model is not interoperable and is deficient in many aspects. That's why the federated identity management model is now emerging and it is very appreciated by enterprises. A federated identity management system consists of software components and protocols that handle in a decentralized manner the identity of individuals throughout their identity life cycle [19].

Solution by Aggregation

Aggregating identity information and finding the relationship between identity records is important to aggregate identity. There are some alternatives:

- The first approach consolidates authentication and attributes in only one site and is called a centralized management solution like Microsoft Passport. This solution avoids the redundancies and inconsistencies in the silo model and gives the user a seamless experience [7]. The evolution was as follows [17,19]:
  - Building a single central identity data store which is feasible only for small organizations.
  - Creating a meta-directory that synchronizes data from other identity data stored elsewhere.
  - Creating a virtual directory that provides a single integrated view of the identity data stored.
  - A Single Sign On Identity model which allows users to be authenticated by one service provider.
- The second approach decentralizes the responsibility of IdP to multiple such IdPs which can be selected by the end users. This is a federate system where some attributes of identity are stored in distributed IdPs. A federated directories model, by linking identity data stored together, has emerged. Protocols are defined in several standards such as in Shibboleth [20], Web services federation language 2003.

Centralized vs. Federation Identity Management

Microsoft Passport is a centralized system, entirely controlled by Microsoft and closely tied to other Microsoft products. Individuals and companies have proven to be reluctant adopters of a system so tightly controlled by one dominant company.

Centrally managed repositories in centralized identity infrastructures can't solve the problem of cross-organizational authentication and authorization. This approach has several drawbacks as the IdP does not only become a single point of failure but may also not be trusted. That's why Microsoft Passport was not successful. In contrast, the federation identity will leave the identity resources in their various distributed locations but produce a federation that links them to solve identity duplication, provision and management.

A Simple Centralized Model

A relatively simple centralized identity management model is to build a platform that centralizes identities. A separate entity acts as an exclusive user credentials provider for all service providers. This approach merges both authentication and attributes in only one site. This architecture, which could be called Common user identity management model, is illustrated in Figure 25.7. All identities for each SP are gathered to a unique identity management site (IdP). SPs have to provide each identity to IdP.

In this environment, users can have access to all service providers using the same set of identifiers and credentials. A centralized certificated CAs could be implemented with a PKI or SPKI [21]. This architecture is very efficient in a close domain where users could be identified by a controlled email address. Although such architecture seems to be scalable, the concentration of privacy related information has a lot of difficulties in social acceptance in terms of privacy [22].

Meta-Directories

SPs can share certain identity-related data on a meta-level. This can be implemented by consolidating all service providers' specific identities to a meta-identifier linked to credentials.

There are collections of directories information from various directory sources. We aggregated them to provide a single view of data. Therefore, we can show these advantages:

- A single point of reference provides an abstraction boundary between application and the actual implementation.
- A single point of administration avoids the multiple directories, too.
- Redundant directory information can be eliminated, reducing the administration tasks.

This approach can be seeing from the user's point of view to his/her password as synchronization across multiple service providers. Thus, the password is automatically changed with all the others.

This architecture can be used in large enterprises where all services are linked to a meta-directory, as shown in Figure 25.8. In this case, the ease-of-use is clear as the administration is done by a single authority.

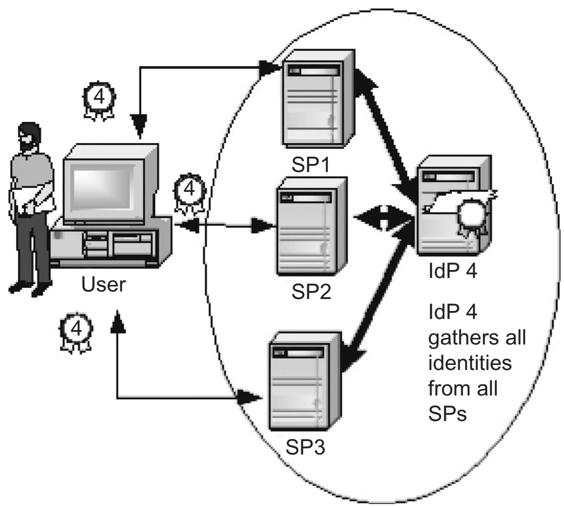

FIGURE 25.7 Simple centralized identity management.

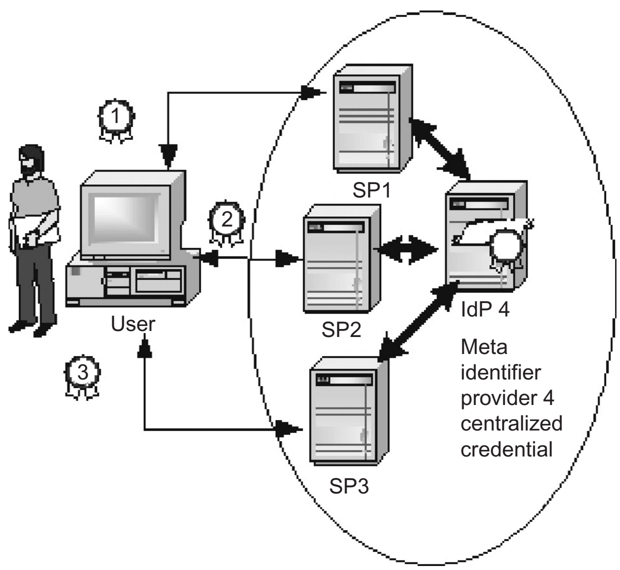

FIGURE 25.8 Meta-directory model.

Virtual Directories

Virtual directories are directories that are not located in the same physical structure as the Web home directory, but look as if they were to Web clients. The actual directories may be at a completely different location in the physical directory structure; for example, on another hard disk or on a remote computer. They are similar in concept to meta-directories in that they provide a single directory view from multiple independent directories. They differ in the means used to accomplish this goal. MD software agents replicate and synchronize data from various directories in what might be batch processes. In contrast, VD provide a single view of multiple directories using real-time queries based on mapping from fields in the virtual scheme to fields in the physical schemes of the real directories.

Single-Sign-On (SSO)

We use multiple user's Ids and passwords just to use the emails systems and file servers at work and we feel pain from managing multiple identities. The second problem is the scattering of identity data which causes problem for the integration of IT systems.

Single Sign-On (see Figure 25.9) is a solution proposed to eliminate multiple password issues and dangerous password. Moreover, it simplifies the end-user experience and enhances security via identity-based access technology. Therefore, it offers these features:

- Flexible authentication,
- Seamless

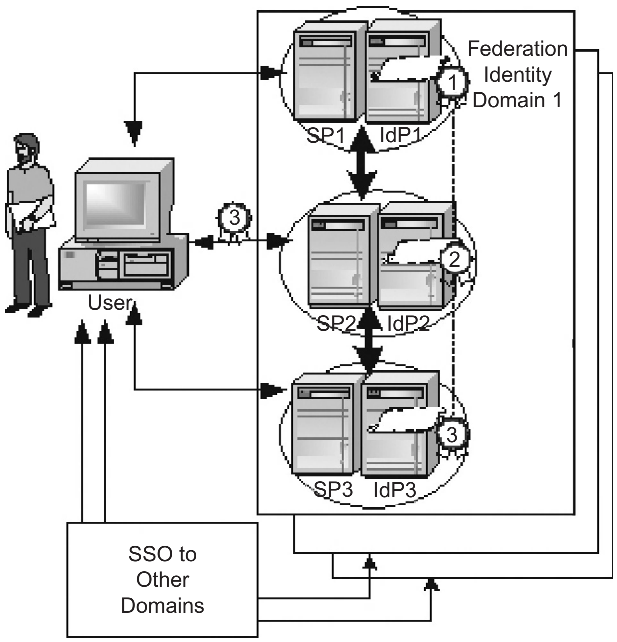

FIGURE 25.9 Single-Sign-On model.

- Directory independence and
- Session and password management.

Federated Identity Management

We have seen different approaches to manage user's identity; they are not clearly interoperable and are deficient in unifying standard-based frameworks. On one hand, maintenance of privacy and identity control are fundamental when offering identity to users, on the other hand the same users ask for more easy to use and rapid access. The balance of the two sides leads to federated network identity. That's why these environments are now emerging. A federated identity management system (See Figure 25.10) consists of software components and protocols that handle the identity of individuals throughout their identity life cycle.

This architecture gives the user the illusion that there is a single identifier authority. Even though the user has many identifiers, he doesn't need to know exactly all of them. Only one identifier is enough to have access to all services in the federated domain.

Each SP is responsible for the name space of his users and all SPs are federated by linking the identity domains. Thus, the Federated identity model is based on a set of SPs called a circle of trust by the Liberty Alliance. This set of SPs follows an agreement on mutual security and authentication in order to allow SSO. Indeed, the federated identity management combines SSO and authorization tools using a number of mutual SPs' technologies and standards. This practice makes the recognition and entitlement of user identities by other SPs easy. The Figure 22-10 shows the set of federated domains and the possibility for other SPs to have access to the same user with different identifiers.

The essential difference between federated identity systems and centralized identity management is that there

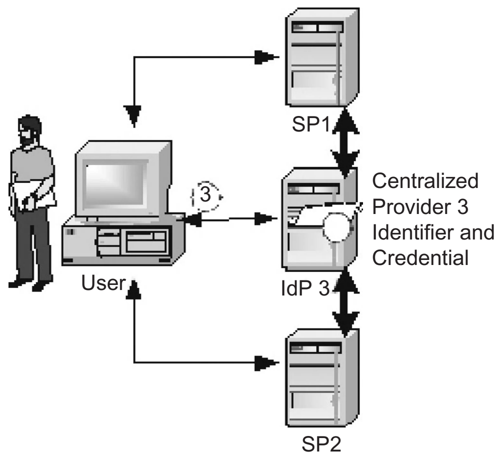

FIGURE 25.10 Federated identity management model.

is no single entity that operates the identity management system. Federated systems support multiple identity providers and a distributed and partitioned store for identity information. Therefore, a federated identity network allows a simplified sign-on to users by giving rapid access to resources, but it doesn't require the user's personal information to be stored centrally. With this identity network approach, users authenticate themselves once and can control how their personal information and preferences are used by the service providers.

Federated identity standards, like those produced by the Liberty Alliance [23], provide Single-Sign-On over all offered services and enable users to manage the sharing of their personal information through identity and service providers as well as the use of personalized services in order to give access to convergent services. The interoperability between disparate security systems is assumed by an encapsulation layer through a trust domain which links a set of trusted service providers.

However there are some disadvantages with federated identity management. The first one is the lack of privacy of the user as his/her personal attributes and information can be mapped using correlation between identifiers. Anonymity could be violated. The second one is the scalability of users as they have access to the network from different domains by authentication to their relative IdPs. Therefore, the problem of passwords will continue across multiple federated domains.

A major challenge is to integrate all these components into a distributed network and to deal with these drawbacks. This challenge cannot be taken up without new paradigms and supported standards.

The evolution of identity management system is toward also simplification of user experience and reinforcing authentication. It is very known that a poor usability implies the weakness of authentication. A new paradigm should be introduced to solve those problems while still being compatible at least with federated identity management.

That is why user-centric identity management, has emerged [7,17]. This paradigm is embraced by multiple industry products and initiative such as Microsoft Cardspace [24], Sxip [25] and Higgins Trust Framework [26]. This is Identity 2.0.

Identity 2.0

The user of Internet services is overwhelmed with identities. he/she is seldom able to transfer his/her identity from one site to another. The reputation that he/she gains in one network is useful to transfer to other networks. Nevertheless, he/she cannot profit from his/her constructed reputation and he/she should rebuild his/her identity and reputation another time, and so on. The actual systems don't allow users to decide about the sharing of their attributes related to their identity with other users. This causes a lack of privacy control. Some solutions propose an advanced social system that would model the social interaction like the real world.

The solutions must be easy to use and enable users to share the credentials among many services and must be transparent from the end-user perspective. The principle of modern identity is to separate the acquisition process from the presentation process. It is the same for the identification process and authorization process. Moreover, it provides scalability and privacy. Doing so, we can have more control on my identity.

The scale, security and usability advantages of user-centric identity are what make it the underpinning for Identity 2.0. The main objective of Identity 2.0 protocol is to provide users with full control over their virtual identities. An important aspect of Identity 2.0 is protection against increasingly Web attacks like Phishing attacks as well as the inadvertent disclosure of confidential information while enabling convenient management.

Identity 2.0 would allow users to use one identity respecting transparency and flexibility. It is focused around the user and not around directory or identity provider. It requires identified transactions between users and relaying party using credentials, thus providing more traceable transactions. To maximize the privacy of users, some credentials could be given to the users in advance. Doing so, the IdP could not easily know when the user is utilizing the credentials.

The Identity 2.0 (See Figure 25.11) endorses completely the paradigms of user-centric identity management enabling the full control of user on his/her identity. Service Provider will therefore be required to change their approaches by including request and authentication

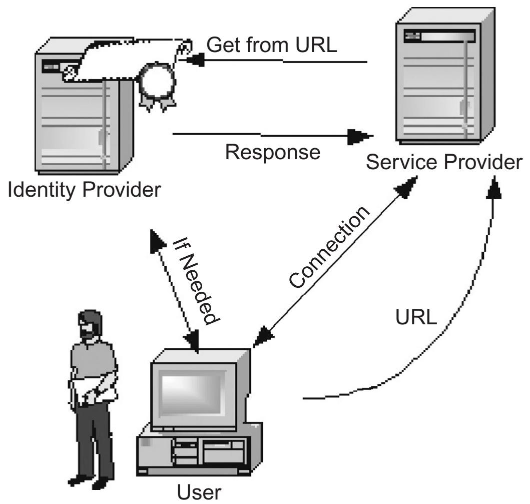

FIGURE 25.11 URL-based Id 2.0.

of users' identity. Identity 2.0 systems are interested in using the concept of a user's identity as credentials about the user, from their attributes like their name, address, to less traditional things like their desires, customer service history, and other attributes that are usually not so much associated with a user identity.

Identity 2.0 Initiatives

When a Website collects data from users he cannot confirm whether or not the collected data is pertinent and reliable as the users often enter nonsense information into online forms. This is due to the lack of Website to control and verify the users' data. Furthermore, due to the law limitation on the requested data, the Website cannot provide true customized services even though users require them. In the other side, users have not direct control on what the Website will do with their data. In addition, the users enter many times the same data when accessing the first time different Websites. Doing so, they have a huge difficulty to manage their large number of identities.

To mitigate these problems, different models of identity management have been considered. One such model, Identity 2.0, proposes an Internet-scalable and user-centric identity architecture that mimics real world interactions.

Many research labs have collaborated to develop the Identity 2.0 Internet based Identity Management services. It is based on the concept of user-centric identity management, supporting enhanced identity verification and privacy, and user consent and control over any access to personal information for Internet-based transactions. There are various Identity 2.0 initiatives:

1. **LID**
2. **XRI**
3. **SAML**
4. **Shibboleth**
5. **ID-WSF**
6. **OpenID**
7. **Microsoft's CardSpace (formerly InfoCard)**
8. **SXIP**
9. **Higgins**

LID

Like LDAP, LID is under the principle of simplicity because many existing identity schemes are too complicated to be largely adoptable. It simplifies more complex protocol; but instead of being less capable due to fewer features, it has run success that their more complex predecessors lacked. This was because their simplification reduced the required complexity to the point where many people could easily support them, and that was one of the goals of LID.

Light-Weight Identity (LID) is a set of protocols capable of representing and using digital identities on the Internet in a simple manner, without relying on any central authority. LID is the original URL-based identity protocol, and part of the OpenID movement.

LID supports digital identities for humans, human organizations and non-humans (software agents, things, Websites, etc.) It implements Yadis, a meta-data discovery service and is pluggable on all levels.

XRI/XDI

We have XRI E**X**tensible **R**esource **I**dentifier (see Figure 25.12) and XDI which fractional solution without Web services integrated. They are open standards as they are royalty-free open standards. XRI is about Addressing. XDI is about Data Sharing protocol and uses basically XRI. Both XRI and XDI are being developed under the support of OASIS. I-name and I-number registry services for privacy-protected digital addressing use XRI. It can be used as an identifier for persons, machines and agents.

XRIs offer a human-friendly form of persistent identifier. That's why it is convenient identifier for SSO system. They Supports both persistent and reassignable identifiers in the same syntax and establish a global context symbols. Moreover, they enable identification of the same logical resource across multiple contexts and multiple versions of the same logical resource.

XDI (XRI Data Exchange) is a Secure Distributed Data Sharing Protocol. It is also an architecture and specification for privacy-controlled data exchange where all data is identified using XRIs. The XDI platform includes explicit specification for caching with both push and pull synchronization. XDI universal schema can represent any complex data and have the ability of cross context addressing and linking.

SAML

The Security Assertion Markup Language (SAML) is an OASIS specification [27] that provides a set of rules for the structure of identity assertions, protocols to move assertions, bindings of protocols for typical message transport mechanisms, and profiles. Indeed, SAML (see Figure 25.13) is a set of XML and SOAP-based services

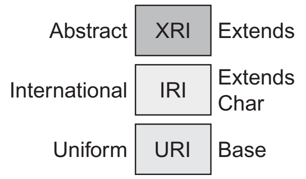

FIGURE 25.12 XRI layers.

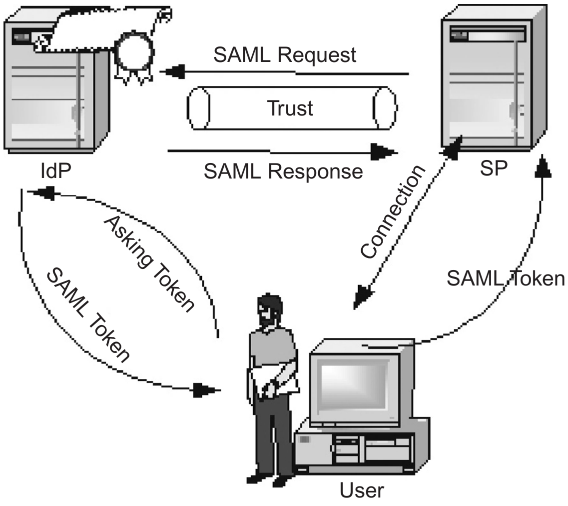

FIGURE 25.13 SAML token exchange.

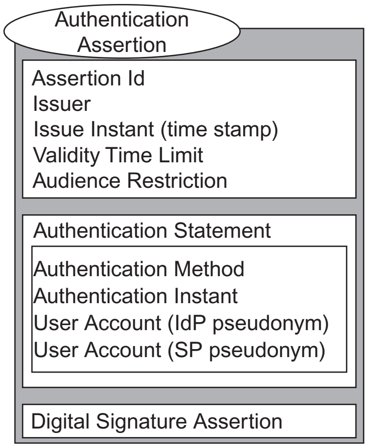

FIGURE 25.14 SAML assertion.

and formats for the exchange of authentication and authorization information between security systems.

The initial versions of SAML v1.0 and v1.1 define protocols for SSO, delegated administration, and policy management. The most recent version is SAML 2.0. It is now a common language to the majority platform to change secure unified assertion. He is very useful and simple as it is based on XML. An assertion is a datum produced by a SAML authority referring to authentication, attribute information, or authorizations applying to the user with respect to a specified resource.

This protocol (see Figure 25.14) enables interoperability between security systems (Browser Single Sign On, Web Services Security, etc.). Other aspects of federated identity management as permission-based attribute sharing are also supported.

An SAML is sometimes criticized for its complexity of the specifications and the relative constraint of its security rules. Recently, the SAML community has shown significant interest in extending SAML to reach less stringent requirements for low-sensitivity use cases. The advantages of SAML are robustness of its security and privacy model, and the guarantee of its interoperability between multiple vendor implementations through the Liberty Alliance's Conformance Program.

Shibboleth

Shibboleth [20] is a project which goal is to allow universities to share the Web resources subject to control access. Thereafter, it allows inter-operation between institutions using it. It develops architectures, policy structure, practical technologies, and an open source implementation. It is building components for both the identity providers and the reliant parties. The key concept

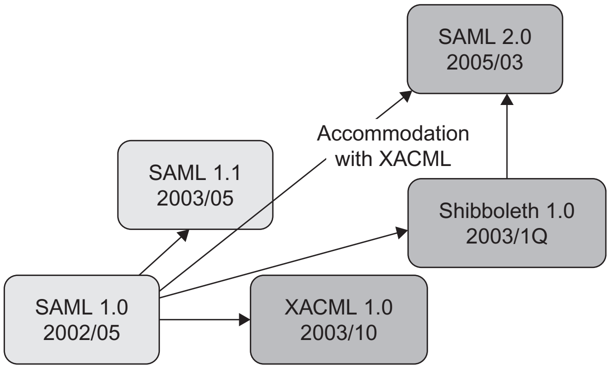

FIGURE 25.15 Convergence between SAML & Shibboleth.

includes "federated" management identity whose meaning is almost the same as the Liberty term's [28]. Access control is fundamentally based on user attributes, validated by SAML Assertions. In Figure 25.15, we can see the evolution of SAML, Shibboleth and XACML [29].

ID-WSF

In 2001, a business alliance was formed to serve as open standards organization for federated identity management and it was named Liberty alliance [23,30]. Its goals are to guaranty interoperability, support privacy, and promote adoption of its specifications, guidelines and best practices. The key objectives of the Liberty Alliance (see Figure 25.16) are to:

- Enable users to protect their privacy and identity
- Enable SPs' to manage their clients
- Provide an open federated SSO
- Provide a network identity infrastructure that supports all current emerging network access devices

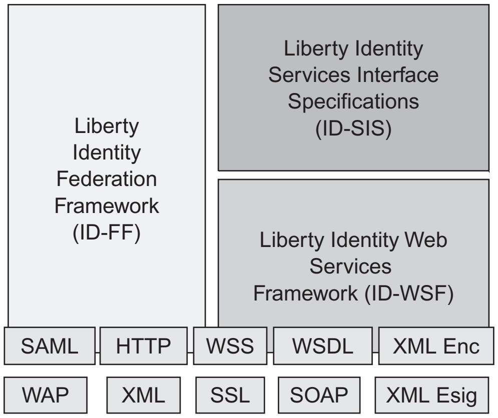

FIGURE 25.16 High-Level Overview of the Liberty Alliance Architecture.

Roadmap to Interoperable Federated Identity Services

The Liberty Alliance's work in the first phase is to enable federated network identity management. It offers among others SSO and linking accounts in the set of SPs' in the boundary of the circle of trust. This work of this phase is referred to as Identity Federation Framework (ID-FF).

In the second phase, the specifications offer enhancing identity federation and interoperable identity-based Web services. This body is referred to as Identity Web Services Framework (ID-WSF). This framework involves support of the new open standard such as WS-Security developed in OASIS. ID-WSF is a platform for the discovery and invocation of identity services — Web services associated with a given identity-. In the typical ID-WSF use case, after a user authenticates to an IdP this fact is asserted to a SP through SAML-based SSO. Embedded within the assertion is information that the SP can optionally use to discover and invoke potentially numerous and distributed identity services for that user. For some scenarios which present an unacceptable privacy risk as it suggests the possibility of a user's identity being exchanged without their consent or even knowledge. ID-WSF has a number of policy mechanisms to guard against this risk but ultimately, it is worth noting that many identity transactions (automated bill payments) already occur without the user's active real-time consent — and users appreciate this efficiency and convenience.

To build additional interoperable identity services such as registration services, contacts, calendar, geo-location services, alert services, it's envisaged to use ID-WSF. This specification is referred to as the Identity Services Interfaces Specifications (ID-SIS).

The Liberty Alliance specifications define the protocol messages, profiles, and processing rules for identity federation and management. They rely heavily on other standards such as SAML and WS-Security which is another OASIS specification that defines mechanisms implemented in SOAP headers.

These mechanisms are designed to enhance SOAP messaging by providing a quality of protection through message integrity, message confidentiality, and single message authentication. Additionally, Liberty has contributed portions of its specification back into the technical committee working on SAML. Other identity management enabling standards include:

- Service Provisioning Markup Language (SPML)
- XML Access Control Markup Language (XACML)
- XML Key Management Specification (XKMS)
- XML Signature
- XML Encryption

The WS-* (the Web Services protocol specifications) are a set of specifications that is currently under development by Microsoft and IBM. It is a part of larger effort to define a security framework for Web services, the resultant of proposals are often referred to as WS-*. It includes specifications as WS-Policy, WS-Security Conversation, WS-Trust, and WS-Federation. This last one has functionality for enabling pseudonyms and attribute-based interactions. Therefore, WS-Trust's has the ability to ensure security tokens as a means of brokering identity and trust across domain boundaries [22].

The Liberty Alliance is developing and delivering specification that enables federate network identity management. Figure 25.16 shows an Overview of the Liberty Alliance architecture as describe in the introduction to the Liberty Alliance identity architecture.

OpenID 2.0

Brad Fitzpatrick is at the origin of the development of the OpenID 1.0. The intent of the OpenID framework is to specify layers that are independent and small enough to be acceptable and adopted by market [12]. OpenID is basically providing simple attribute sharing for low-value transactions. It does not depend on any preconfigured trust model. The version 1.0 has deal with http based URL authentication protocol. OpenID authentication 2.0 is becoming an open platform that supports both URL and XRI user identifiers. In addition, it would like to be modular, lightweight and user oriented. Indeed, OpenID auth. 2.0 allows user to choose/control/manage his/her identity address. Moreover, the user choose his/her Identity Provider and have a large interoperability of his/her identity and can dynamically uses new services that stand out attribute verification and reputation without any loose of features. No software is required on user's side as the user interacts directly with the identity provider's

site. This approach jeopardize the user identity because it could be hacked or theft. Moreover the user has no ability to examine tokens before they are sent.

At the beginning of identity management each technology came with its own futures without any interest for others. Later, the OpenID 1.0 community has realized the importance of integrating other technologies as OASIS XRDS which is useful for his simplicity and extensibility.

OpenID Stack

The first layer is for supporting users' identification. Using URL or XRI form, we can identify an user. URL use IP or DNS resolution and is unique and ubiquitously supported. It can be as a personal digital address as used by blogers even though it is not yet largely used.

XRI (EXtensible Resource Identifier) is being developed under the support of OASIS and is about Addressing. I-names are a generic term for XRI authority names that provide abstract identifiers for the entity to which they are assigned. They can be used as the entry point to access data under the control of that authority. Like a domain name, the physical location of the information is transparent to the requester.

OpenID 2.O provides a private digital address to allow a user to be only identified in specific conditions. This is guaranty the user privacy in a public domain.

Discovery Yadis is used for identity service discovery for URLs and XRI resolution protocol for XRIs. The both use OASIS format called XRDS (Extensible Resource Description Sequence). The protocol is simple and describes any type of service.

Authentication This service lets a user to prove his/her URL or I-name using credentials (cryptographic proof). This protocol is explained in Figure 25.17. The OpenID doesn't need a centralized authority for enrollment and it is therefore a federated identity management. With the OpenID 2.0 the IdP offers the user the option of selecting a digital address to send to the SP. To ensure anonymity, IdP can randomly generate a digital address used specially for this SP.

Data Transport This layer ensures the data exchange between the IdP and SP. It supports push and pulls methods and it is independent from authentication procedures. Therefore, the synchronization of data and secure messaging and other service will be enabled. The data formats are those defined by SAML, SDI (XRI Data interchange) or any other data formats. This approach will enable evolution of the OpenID platform.

The four layers construct the foundation of the OpenID ensuring user centricity (see Figure 25.18). There are three points to guaranty this paradigm:

1. User choose his/her digital identity
2. User choose IdP
3. User choose SP

OpenID is decentralized and well founded and at the same time simple, easy to use and to deploy. It provides open development process and single sign-on for the Web and ease of integration into scripted Web platforms (Drupal, WordPress, etc).

So, it is a greater future for him. You can learn about OpenID at openidenabled.com also the community of OpenId can be joined at opened.net.

InfoCard

Rather than invent another technology for creating and representing digital identities, Microsoft has adopted the federated user-centric identity meta-system. This is a serious solution that provides a consistent way to work with multiple digital identities. Using standard protocols that anyone can implement on any platform, the identity

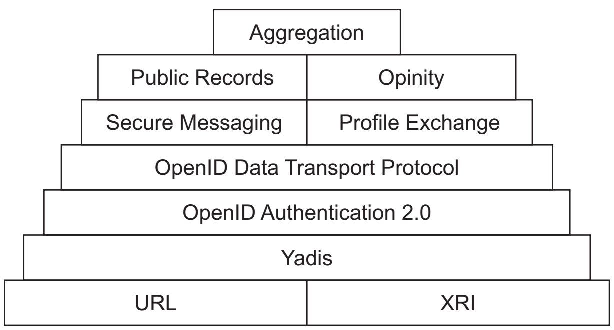

FIGURE 25.17 OpenID protocol stack.

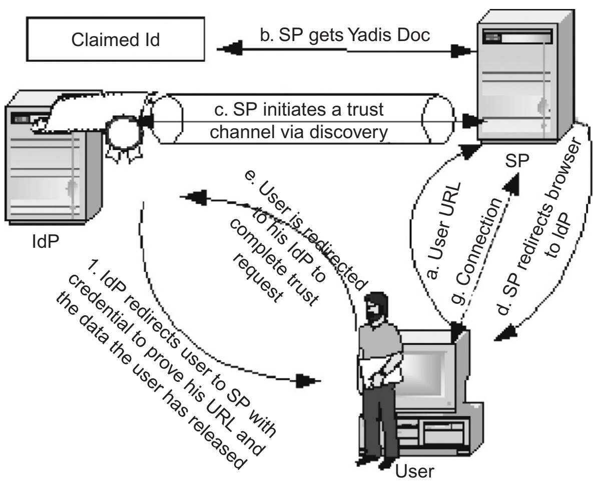

FIGURE 25.18 OpenID 1.1 protocol flow.

meta-system allows the acquisition and use of any kind of security tokens to convey identity.

The "Infocard" is the Microsoft's codename for this new technology that tackles the problem of managing and disclosing identity information. The "InfoCard" implements the core of the Identity Metasystem, using open standard protocols to negotiate, request and broker identity information between trusted IdPs and SPs. "InfoCard" is a technology that helps developers to integrate a consistent identity infrastructure into applications, Web sites and Web services.

By providing a way for users to select identities and more, Windows CardSpace [24] plays an important part in the identity meta-system.

It provides the consistent user experience required by the identity meta-system. It is specifically hardened against tampering and spoofing to protect the end user's digital identities and maintain end-user control. Windows CardSpace enables users to provide their digital identities in a familiar, secure and easy way.

In the terminology of Microsoft, relying party is in our model service provider (SP). To prove an identity over a network, the user emitted credentials which are some proofs about his/her identity. For example in the simplest digital identity the user name is the identity while the password is said to be the authentication credential. In the terminology of Microsoft and others, there are called security token and contain one or more claims. Each claim contains information about the users, like the user name or home address, etc. In addition, security token encloses prove that the claims are correctly emitted by the real user and are belonging to him. This is could be done cryptographically using different forms such as X.509 certificates and Kerberos tickets but unfortunately there are not practical to convoy different kind of claim. The standard SAML as seen before is the indicated one for this purpose as it can be used to define security tokens. Indeed, SAML token could enclose any desired information and thus become as largely useful in the network to show and control digital identity. CardSpace runs on Windows Vista, XP, Server 2003 and Server 2008, based on .NET3, and also uses Web service protocols:

- WS-Trust
- WS-Policy
- WS-SecurityPolicy
- WS-MetaDataExchange

CardSpace runs in a self virtual desktop on the PC. Thereby, it locks out other processes and reduces the possibility of intercepting information by a spyware.

Figure 25.19 shows that the architecture is fitting exactly to the principle of Identity 2.0. The user access one of any of his/her relying parties (SPs) using an application that supports CardSpace.

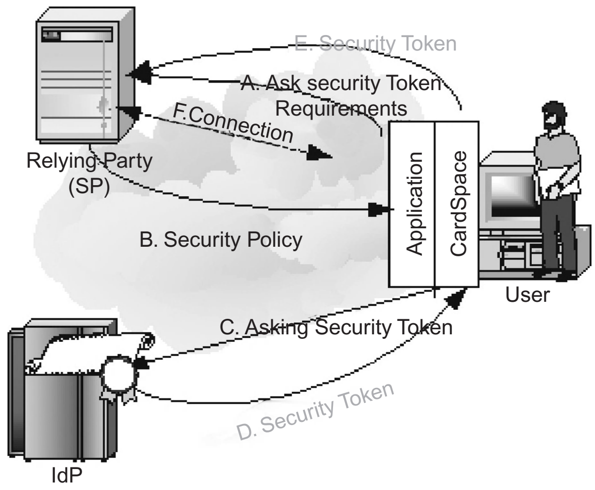

FIGURE 25.19 Interactions among the users, identity providers and relying party.

When the choice is made, the application asks for the requirement of security token of this specific SP that will answer with SP policy. It really contains information about the claims and the accepted token formats. Once this is done, the application passes these requirements to CardSpace which asks the security token from an appropriate identity provider.

Once this security token has been received, CardSpace transmits via application to the relying party. The relying party can then use this token to authenticate the user.

Please note that each identity is emitted by an identity provider and is stored at the user side. It contains the emitter, the kind of security token he/she can issue and the details about the claims' enclose. All difficulties are hidden to the user as he/she has only to choose one of InfoCard when the process of authentication is launched. Indeed, once the requirements information are returned and passed to CardSpace, the system displays the card selection matching the requirements on screen. In this regard, the user has a consistent experience as all applications based on CardSpace will have the same interface, and the user do not have to worry about the protocol used to express identity's security token. The PIN number is entered by user and the choice of his/her card is done in a private Windows desktop to prevent locally-running process.

SXIP 2.0

In 2004, The SXIP 1.0 grows from efforts to build a balanced online identity solution that met the requirements of the entire online community. Indeed, SXIP 2.0 is the new generation of the SXIP 1.0 protocol that was a platform that gives users control over their online identities and enables online communities to have a richer

relationship with their membership. SXIP 2.0 defines entities' terminology as:

- Homesite: URL-based identity given by IdP.
- Membersite: SP that uses SXIP 2.0.
- User: equivalent to the user in our model.

The Simple eXtensible Identity Protocol (SXIP) [25] was designed to address the principles defined by the Identity 2.0 model (see Figure 25.20), which proposes an Internet-scalable and user-centric identity architecture that mimics real-world interactions.

If a SP has integrated a SXIP to his Website, which is easy done by using SDKs, he is a Membersite. When a subscriber of SXIP would like to access this Membersite:

1. Types his/her URL address and clicks on [Sxip in]
2. Types his/her URL identity issued by IdP (called Homesite)
3. Browser is redirected to the Homesite
4. Enters his/her username and password, being informed that the Membersite has requested data, selects the related data and verify it and can select to automatically release data for other visit to this Membersite and confirms
5. Browser is redirected to the Membersite
6. Have access to the content of the site.

SXIP 2.0 is a platform based on a fully decentralized architecture providing an open and simple set of process for exchanging identity information. SXIP 2.0 has significantly reduced the problems resulting from moving identity data form one site to another. It is URL-based protocol that allows a seamless user experience and fits exactly to user-centric paradigm. In that sense, the user

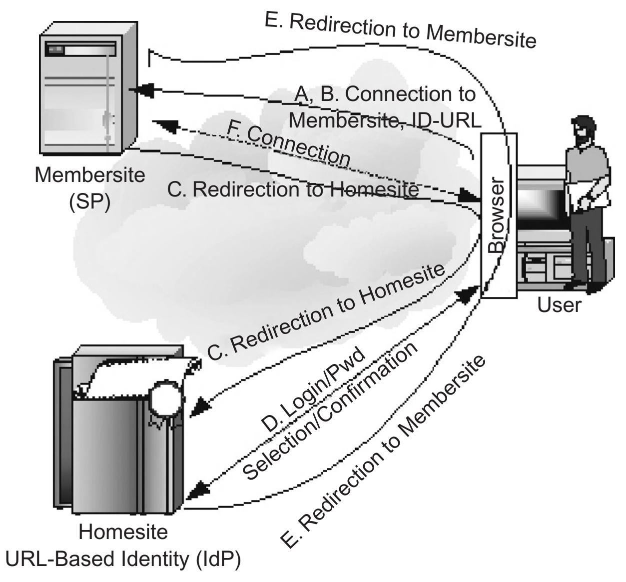

FIGURE 25.20 SXIP entities interactions.

has full control on his/her identity and has an active role in the exchange of his/her identity data. Therefore, he/she can profit from portable authentication to connect many Websites. Doing so, user has more choice and convenience when exchanging his/her identity data and enables indirectly Websites to offer enhanced services to their subscribers.

SXIP 2.0 provides the following features:

- Decentralized architecture: SXIP 2.0 is completely decentralized and is a federated identity management. The online identity is URL-based and the user identity is separated from the authority that issues the identifiers for this identity. In this regard, we can easily move the location of the identity data without losing the associated identifier.
- Dynamic discovery: A simple and dynamic discovery mechanism ensures that users are always informed online about his/her home site that is exporting identity data.
- Simple implementation: SXIP 2.0 is open source using different high level development languages such as Perl, Python, PHP, and Java. Therefore, the integration of SXIP 2.0 into a Website is effortless. It does not require PKI as it uses a URL-based protocol that do not need it.
- Support for existing technologies: SXIP 2.0 uses simple Web browsers, the primary client and means of data exchange, providing users with choice in the release of their identity data.
- Interoperability: SXIP 2.0 can coexist with other URL-based protocols.
- Richer data at an Internet scale: SXIP 2.0 messages consist of lists of simple name value pairs. It can exchanged simple text, claims using SAML and third-party claims in one exchange and present them in many separate exchange. In addition, the Identity provider is not bothersome every time identity is requested.

Finally by using SXIP 2.0, Websites can also be authoritative about users for data, such as third-party claims. Those are keys to build online reputation, further enriching the online exchange of identity data.

Higgins

Higgins [31] is a project supported principally by IBM and it is a part of IBM's Eclipse open source foundation. It will also offer libraries for Java, C and C++, and plug-ins for popular browsers. It is really an open source trust framework which goals are to support existing and new applications that give users more convenience, privacy and control over their identity information. The aim objective is to develop an extensible,

platform-independent, identity protocol-independent, software framework that provides a foundation for user-centric identity management. Indeed, it enables applications to integrate identity, profiles and relationship across heterogeneous systems.

The main goal of Higgins as an identity management systems are interoperability, security and privacy that are a decoupled architecture. This system is a real user-centric based on a federated identity management. The user has the ability to use a pseudonym or simply reply anonymously in case you would not give your name.

We use the term context to cover a range of underlying implementations. A context can be thought of as a distributed container-like object that contains digital identities of multiple people or processes. The platform intends to address four challenges:

- The need to manage multiple contexts,
- The need for interoperability,
- The need to respond to regulatory, public or customer pressure to implement solutions based on trusted infrastructure that offers security and privacy, and
- The lack of common interfaces to identity/networking systems.

Higgins matches exactly the user-centric paradigms because it offers consistent user experience based on card icons for the management and release of identity data. Thereby, there is less vulnerability to Phishing and other attacks. Moreover, user privacy is enabled by sharing only what is needed. Thus, the user has a full control on his/her personal data. Identity Attribute Service enables aggregation and federation of identity systems and even silos. For enterprises, it integrates all data related to identity, profile, reputation, and relationship information across and among complex systems.

Higgins is a trust framework that enables users and enterprises to adopt, share across multiple systems and integrate to new or existing application, digital identity, profiles, and cross-relationship information. In fact, it facilitates as well the integration of different identity management systems as the management of identity, profile, reputation and relationship data across repositories. Using context providers, directories and communications technologies (Microsoft/IBM WS-*, LDAP, email, etc.) can be plugged into the Higgins framework. Higgins has become an Eclipse plug-in, and is a project of the Eclipse Foundation. Any application developed with Higgins will enable users to share identity with other users under a strict control.

Higgins is benefic for developers, users and enterprise. Higgins relieves the developers from knowing all the details of multiple identity systems, thanks to one API that support many protocols and technologies: CardSpace, OpenID, XRI, LDAP, etc. An Application written to the Higgins API can integrate the identity, profile, and relationship information across these heterogeneous systems. The goal of the framework is to be useful in the development of applications accessed through browsers, rich clients, and Web services. Thus, the Higgins Project is supported by IBM and Novell and thwart InfoCard Microsoft's project.

The Higgins framework intents to define in terms of service descriptions, messages and port types consistent with an SOA model and to develop a Java binding and implementation as an initial reference. Applications can use Higgins to create a unified, virtual view of identity, profile and relationship information. A key focus of Higgins is providing a foundation for new "user-centric identity" and personal information management applications.

Finally, Higgins provides virtual integration; user-centric federated management model and trust brokering that are applied to identity, profile and relationship information. Furthermore, Higgins provides common interfaces to identity and thanks to data context it encloses enhanced automation process. Those features are also offered across multiple contexts, disparate systems and implementations. In this regard, Higgins is a full interoperable framework.

The Higgins service acts together with a set of so-called context providers which can represent a department, association, informal network and so on. A context is the environment of Higgins and digital identities, the policies and protocols that govern their interactions. Context providers adjust existing legacy systems to the framework, or implement new one*s* Context providers may also contain the identities of a machine or human. A context encloses a group of digital identities and their related claims and links. A Context maintains a set of Claims about properties and values (name, address, etc.). It is like security token for Cardspace. The set of profile properties, the set of roles, and the access rights for each role are defined by and controlled by the Context Provider.

Context providers act as adapters to existing systems. Adapter providers can connect for example to LDAP servers, identity management systems like CardSpace, mailing list and social networking systems. A Higgins context provider (see Figure 25.21) has the ability to implement the Context interface and thus empower the applications layered on top of Higgins.

Summarizing Table

The 10 requirements at the top of Table 25.1, are those discussed earlier in the chapter. In this table, white means that the requirement is not covered, grey partially and black fully fulfilled.

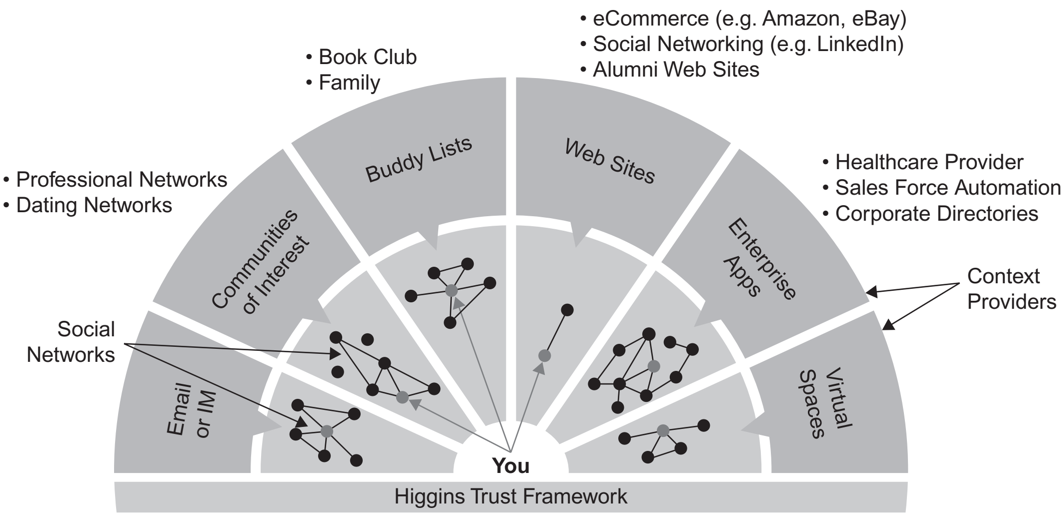

FIGURE 25.21 Higgins Trust Framework and context [26].

At the moment, service providers have to choose between so many authentications and identity management systems and users are left to face the non-convenience of a variety of digital identities. The main initiatives have different priorities and some unique advantages, while overlapping in many areas. The most pressing requirements for users are interoperability, usability and centricity. Thanks to Higgins the majority of identity requirements are guaranty. Therefore, using it, the user is free to visit all Web sites without being worried about the identity management system used by the provider.

5. SOCIAL LOGIN AND USER MANAGEMENT

At the time of the writing of the second version of this book chapter (end of 2012), none of the identity management technologies surveyed earlier in the chapter, have reached major user adoption. A few of them have been discontinued. For example, Sxip went bankrupt [32]. Others have moved very slowly. Higgins has only released a partial implementation of its vision and seems on hold. Liberty Alliance moved to a new initiative called the Kantara initiative [23]. However, a new type of solutions, which was not really expected at time of writing the first version of the book chapter, has emerged and gained quite large users adoption. This type of solutions is provided by major online social networks that have reached mass market very fast and where users have spent time configuring their profile. Then, those major online networks have built on top of previously surveyed standard identity management technological building blocks tools to facilitate logging to other Web sites and online services with the identities managed on their services. The good news is that most of them have based their work on OpenID. Therefore although OpenID is less known by the greater public, it still exists underneath. They are also extensively relying on OAuth [33] that was built when OpenID was investigated for Twitter [34]. It is also possible to authenticate through OAuth but OAuth goes beyond OpenID regarding authorizations (in addition to authentication). The major online social networks providers that have created tools to allow their users to easy log in into other Web sites and services are: Facebook [35], Twitter, LinkedIn [36] and Google [37].

The Web sites and services that use the “social login” tools of one of these providers provide an easier access to their service to users who already have an account on this external provider. With a few confirming clicks, the user has joined the new service without having to spend time filling out her personal information again. Although this solution has gained large adoption because it fulfilled the user-friendliness requirement, there are still a few flaws remaining.

First, there is concern about the privacy protection requirement. For example, based on Facebook privacy bugs and issues due to privacy protection laws in different countries, one cannot claim that a Facebook user is really under control of her personal data disclosed to Facebook. It does not correspond to a user-centric approach. Thus, the Web site or service that reuses Facebook identity management service does not really fulfill the privacy requirement discussed above. The same privacy issues apply to the other “social login” providers.

Second issue concerns allowing users who may not have an account in one of the chosen “social login” provider to still login. Although the “social login” providers have created tools to connect their identity management

TABLE 25.1 Evaluation of Identity 2.0 Technologies.

Requirement	Empowering the total control of users over their privacy rivacy	Usability, as users are using the same identity for each identity transaction	Giving a consistent user's experience thanks to uniformity of identity interface	Limiting identity attacks i.e. phishing	Limiting reachability/ disturbances, such as spam	Reviewing policies on both sides when necessary, identity providers and service providers	Huge scalability advantages as the identity provider does not have to get any prior knowledge about the service provider	Assuring secure conditions when exchanging data	Decoupling digital identity from applications	Pluralism of operators and technologies

OpenID										
SXIP										
Higgins										

system to another Web site or service, adding multiple login forms to a Web site or service takes times and may confuse the user as many forms may be possible for registering. In addition, most "social login" providers often change their Application Programming Interface (API) without backward compatibility. Thus, the Web site or service may lose its registration functionality for some time before it can apply the required changes.

It is why a new type of providers has emerged on top of these "social login" providers. Those providers do the hard work to maintain a tool that allows a user to create an account with all the "social login" providers as well as store and manage users information on behalf of the service or Web site that uses this tool. The owners of Web sites and services install this tool on their Web site or service without having to worry when one of the "social login" providers change their API. The price of allowing a user to create an account with any of the main online social networks providers without having to maintain each "social login" module has to be weighed against the subscription price to one of these user management providers such as Janrain [38], OneAll [39], LoginRadius [40] or Gigya [41].

6. IDENTITY 2.0 FOR MOBILE USERS

In this section, we discuss identity management in the realm of mobile computing devices. These devices are used more and more, and have different constraints than fixed desktop computers.

Introduction

The number of devices such as mobile phones, smart cards and RFIDs [42], is increasing daily and becoming huge. Mobile phones have attracted particular interest because of their large penetration and pervasiveness that exceeds that of personal computers. Furthermore, the emergence of both IP-TV and wireless technology has facilitated the proliferation of intelligent devices, mobile phones, RFIDs, and other forms of information technology that are developing at a rapid speed. These devices include a fixed identifier that could be linked to the user's identity. This identifier provides a mobile identity which takes into account information about the location and the mobile user's personal data [43].

Mobile Web 2.0

Mobile Web 2.0 as a content-based service is an up-to-date offering of services within the mobile network. As the number of people having access to mobile devices exceeds those using a desktop computer, *mobile Web* will be a key factor for the next generation network. At the moment, mobile Web suffers from lack of interoperability and usability due to the small screen size and lower computational capability. Fortunately, these limitations are only temporary and within 5 years they will be easily overcome. There will be convergence in the next generation public networks towards the mobile network which will bring mobility to the forefront. Thus, mobile identity management will play a central role in addressing issues such as usability, privacy and security which are key challenges for researcher in the mobile network. Since the initial launch of mobile Web services, customers have increasingly turned to their wireless phones to connect with family and friends and also to obtain the latest news and information or even to produce content with their mobile and then publish them. Mobile Web 2.0 [27] is the enforcement of evolution and will enhance the experience of users by providing connections in an easier and more efficient way. For this reason, it will be welcome by the key actors as a well-established core service identity management for the next generation mobile network. This mobile identity management will be used not only to identify, acquire, access and pay for services but also to offer context-aware services as well as location based services.

Mobility

The mobile identity may not be stored at the same location but could be distributed among many locations, authorities and devices. Indeed, identity is mobile in many respects [1]:

1. There is a device mobility where a person is using the same identity while using different devices;
2. There is a location mobility where a person is using the same devices while changing the location; and
3. There is context mobility where a person is receiving services based on different societal roles: as a parent, as a professional and so on.

The three kind of mobility are not isolated but they interacted more often and became concurrently modified creating much more complex situations that what implied from single mode. Mobile identity management addresses three main challenges: a. usability via context awareness b. trust based on the perception of secure operation and c. the protection of privacy [1].

Evolution of Mobile Identity
